Embryo culture of a tomato species hybrid, P. G. SMITH. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc., 44* (*1944*), *pp. 413–416, illus. 1*).—A record is presented of an attempt to obtain hybrids between *Lycopersicon esculentum* and *L. peruvianum* by the use of the embryo culture technic. From a total of 50-odd dissected embryos, 3 were cultured and attained a size suitable for transplanting into soil. In all the crosses, the cultivated tomato Michigan State Forcing was used as the ovule parent. Although normal-appearing fruits were produced, most of the seeds contained minute collapsed ovules with an occasional enlarged ovule with a partially developed embryo. Only those fruits that made rapid development on vigorous healthy plants contained these partially developed embryos. The embryos that grew developed rapidly when transferred to the nutrient medium. The plants were vigorous, and bloomed freely, but the flowers were self-sterile. No seed was produced with *L. esculentum* pollen, but in the backcross to the *L. peruvianum* parent there was obtained seed some of which contained apparently normal embryos. The project has had to be suspended for the duration of the war.

Genetic proof of heterokaryosis in Penicillium notatum, G. PONTECORVO and A. R. GEMMELL (*Nature* [*London*], *154* (*1944*), *No. 3912, pp. 514–515, illus. 1*).—In this note the author states that previous "cytological inference, in the case of *P. notatum,* needs the support of a genetic counterproof—this can now be supplied." Brief details are presented of the results of production by X-rays of mutant strains, mixed inoculations two by two of different mutant strains, and search for nonmutant ("wild type") patches or for patches differing from either strain at the center of the mixed colony and along the radii where the mycelia of the two strains contact.

Mendelian inheritance of adaptive enzymes in yeast, C. C. LINDEGREN, S. SPIEGELMAN, and G. LINDEGREN (*Natl. Acad. Sci. Proc., 30* (*1944*), *No. 11, pp.*

346–352, illus. 2).—*Saccharomyces carlsbergensis* and its haploid segregants adapted themselves to melibiose fermentation; *S. cerevisiae* and its haplophase did not Data from 175 progenies of the interspecific and related hybrids were consistent with the view that *S. carlsbergenesis* contains two pairs of dominant genes, each of which controls the production of an adaptive enzyme. The gene initiates the synthesis of a melibiose-fermenting enzyme complex, providing melibiose is present *S. cerevisiae* is homozygous for the recessive allels.

What is germ plasm? G. T. HARGITT (*Science, 100 (1944), No. 2599, pp. 343–348*).—It is contended that the term "germ plasm" has been so generally used, with diverse meanings, by laymen and biologists that a clear understanding or appreciation of the underlying molecular phenomena, which are fundamental and significant, may be prevented.

The heredity of smooth tongue, with special reference to cattle, T. DE GROOT (*Genetica ['s Gravenhage], 23 (1942), No. 2, pp. 221–246, illus. 14*).—Epitheliogenesis imperfecta linguae bovis, which has become very widespread among the cattle of the Netherlands, was found from a study of the pedigrees of 350 abnormal animals and the distribution of 90 normals to 38 smooth-tongued individuals in the F_2 generation to indicate that the defect or tendency to develop it depends on a simple autosomal recessive factor. For the most progress in ridding the herd of the abnormality, all parents of defectives should be eliminated. The similarity to the condition described by I. Lundholm[1] in man as hereditary hypochromic anemia is noted.

Prevalence of "wrytail" in cattle, F. W. ATKESON, F. ELDRIDGE, and H. L. IBSEN. (Kans. State Col.). (*Guernsey Breeders' Jour., 66 (1944), No. 8, pp. 785–787, illus. 2*).—Confirmation was given to the inheritance of wry tail (E. S. R., 74, p. 622) as a recessive character due to a gene frequency of 57.8 percent in 10 Jersey herds totaling 350 head, in which there were 117 animals with wry tails. There was practically equal distribution of wry tail to the left or to the right regardless of this characteristic in the parents of wry-tailed progeny, indicating that the direction of the tail set is nongenetic. The character has been observed in the other dairy breeds, but sufficient evidence is not available to determine if the mode of inheritance is the same as that found in the Jersey and Brown Swiss.

Can we breed up Holstein test? J. [W.] BARTLETT. (N. J. Expt. Stas.). (*Holstein-Friesian World, 41 (1944), No. 20, pp. 13–14, 115–116, illus. 2*).—Study of the development of the Holstein herd inbred for 12 yr. showed that dairy cattle may be profitably inbred but that rigid selection must be followed. Animals carrying undesirable genes may be eliminated and attention concentrated on desirable qualities for size, breed type, percentage of fat, and milk production. When the same sires were used, inbreeding raised the percentage of fat twice as fast as outbreeding without significantly modifying the milk production. This has been essentially noted (E. S. R., 91, p. 530).

Histological studies of boar testes, W. W. GREEN and L. M. WINTERS. (Minn. Expt. Sta.). (*Jour. Morphol., 75 (1944), No. 2, pp. 291–301, illus. 5*).—The rate of testicular development of boars castrated at 8–28 weeks of age was ascertained by histological studies. There were significant differences between inbred groups in the rate of increase of testicular weight and numbers of spermatogonia and primary spermatocytes and in the absolute number of spermatogonia per seminiferous tubule cross section and number and diameter of Leydig cells. There were no group differences in the diameter or rate of increase in the diameter of seminiferous tubules. It was thus evident that genetic constitution of the animal should be considered when studying testicular development. This was more closely related to body weight than age; the left testis was heavier than the right, and season of farrow possibly influenced the rate of testicular development, but these differences were not statistically significant. As line differences have been found in growth responses to castration, sexual activity of boars, time of puberty, 17-ketosteroid excretion, fertility and growth rate, red cell count, hemoglobin, and serum protein content of the blood, it is not surprising to find differences within these lines in the rate of testicular development.

---

[1] Acta Med. Scand., Sup. 102 (1939), pp. 273+, illus. 1.

Lateral hermaphroditism (gynandromorphism) in a pig, C. E. Brown (*Vet. Med., 39 (1944), No. 12, pp. 456–457, illus. 2*).—A pig on autopsy was shown to have an ovary and a testicle at the end of the left and right uterine horns, respectively.

Size of vulva and its relation to fertility in foxes, C. P. Pearson and C. F. Bassett (*Amer. Fur Breeder, 17 (1944), No. 5, pp. 12, 14, illus. 4*).—The average maximum arbitrary vulva size of 115 yearling vixens was 5.42 ± 0.06, whereas with 190 adults the average was 6.60 ± 0.05. Differences between the vulva size of yearlings and 2- and 3-year-olds were significant, but differences between the second- and third-year-olds were not significant. The maximum size of the vulva of vixens was related in successive years. Rating the vulva size from 1 to 9 for each individual, there was an increase of 0.75 pup with each increase of one grade among adult vixens, and 0.45 pup with yearling vixens.

Another case of a black-blue mosaic in the Dutch rabbit, S. E. Smith. (U. S. D. A.). (*Jour. Hered., 35 (1944), No. 11, pp. 325–326, illus. 1*).—A mosaic female rabbit at the U. S. Plant, Soil, and Nutrition Laboratory was born of black Dutch parents. On breeding tests with her sire there were produced 14 progeny of which 7 were black Dutch, 1 was blue Dutch, and 6 were albinos. These results were taken to indicate that this mosaic was heterozygous for the dilution factor *i* and the color factor *c*. It is assumed that the mosaic area resulted from somatic mutation of *I* to *i*, so that the cells of that area have the *ii* genotype which in this case produced a blue color. The genetics of such rabbit mosaic has been discussed by Castle (E. S. R., 83, p. 608).

Absence of potentiation of gonadotropin and steroid function in mammals by colchicine, M. K. McPhail and K. M. Wilbur (*Endocrinology, 35 (1944), No. 3, pp. 196–197*).—No significant effect was induced by colchicine on ovulation in the rabbit or growth of the immature mouse ovary, both induced by pregnant mare serum, or on the size of the prostate gland and seminal vesicles of castrated rats injected with testosterone propionate. These results were based on 12 pairs of rabbits and 14 mice injected with pregnant mare serum and 13 mice in which saline was used in place of colchicine. The study of the seminal vesicles and prostates of castrated rats was made with 3 groups of 8 animals, 1 group of which received testosterone, another testosterone and colchicine, and a third received neither.

Alkaline phosphatase in the ovarian follicles and corpora lutea, G. W. Corner (*Science, 100 (1944), No. 2595, pp. 270–271*).—Histological study of mature follicles of sows in estrus showed that the cells of the theca interna were heavily laden with black granules, indicating the presence of phosphatase, whereas the cytoplasm of the granulosa cells was entirely free of the enzyme. This difference persisted after ovulation and during organization of the corpora lutea. On the contrary, mature follicles from a rabbit 9 hr. after mating showed a strong concentration of phosphatase in the granulosa but none in the theca interna. In corpora lutea about 8 hr., 3 days, and 5 days old, respectively, the lutein cells were laden with the enzyme. Possibly the finding of no granules is because of examining only retrogressive corpora lutea. A heavy black deposit representing phosphatase was found in the theca interna, and a light deposit of the guinea pig in estrus. There seemed to be some variation in the presence of phosphatase in human corpora lutea of different ages. In six species studied, five different conditions existed. The presence of the enzyme seemed to be related to the metabolism of fat.

Effect of thiamin deficiency and controlled inanition on ovarian function, V. A. Drill and M. W. Burrill (*Endocrinology, 35 (1944), No. 3, pp. 187–192, illus. 2*).—In two experiments, estrous cycles ceased in thiamine-deficient normal rats after 16–24 days. Similar responses were noted by other groups of rats subjected to the same feed intake but with adequate thiamine. Diminished gonadotropic function of the pituitary was assumed to be the primary cause of the ovarian hypofunction and the persistent diestrus, except in one of the seven thiamine-deficient rats in the first experiment and two of the eight in the second. There were like numbers of inanition controls in these studies.

Influence of reproductive hormones upon growth in ovariectomized and normal female rats, R. Bogart, J. F. Lasley, and D. T. Mayer. (Mo. Expt. Sta.). (*Endocrinology, 35 (1944), No. 3, pp. 173–181*).—The growth rate of normal and ovariectomized female rats was retarded by the injection of estrone, and the retardation was greatest in the prepubertal animals and in ovariectomized rats when growth rate was most rapid. The quantity of estrone necessary to retard growth in ovariectomized rats in proportion to that in unoperated controls was between 10 and 40 International Units per day. These amounts were within the physiological level of estrogen production of the postpubertal virgin female. Progesterone accelerated growth rate, the greatest acceleration occurring when the growth rate was at a minimum. It seemed to make no difference whether the hormone was injected or produced in pseudopregnancy or pregnancy. However, pregnancy gave a more pronounced stimulus to growth. The growth rate changes were not due to differences in the fat or water content of the carcass, indicating the part played by other factors. There were used in the study groups of 3 to 16 normal and ovariectomized prepubertal and pubertal rats. Groups of ovariectomized rats received different amounts and rates of treatments with estrone for 110 days, and the weights were ascertained at periodic intervals to 164 days. In another group females were mated with vasectomized males for study of the effects of pseudopregnancy. The effect of estrone and ovariectomy were investigated in the fat and water of the carcasses from animals subjected to autopsy.

The development of reactivity in the accessory reproductive organs of castrated and spayed rats injected with testosterone propionate, D. Price (*Physiol. Zool., 17 (1944), No. 4, pp. 377–391, illus. 6*).—The responsiveness of the gonads and accessory reproductive organs of castrated and spayed rats to exogenous hormones was found to depend on the age of the treated animals as well as on other conditions. Males and females gonadectomized at 8 days of age were injected daily for 6 days with graded doses of testosterone propionate beginning at 8, 20, 30, 50, and 70 days of age. In another series of experiments males were castrated at 20, 30, 50, or 70 days of age and injected immediately for the 6-day period as in the first experiment. The minimum effective dose for responsiveness by the male prostate at 8–13 days was 1 μg. daily, but better development occurred at more advanced age, so that the minimum effective dose was 5 μg. at 36–56 days and 10 μg. at 76 days. The responsiveness was maintained in the prostate through the seventy-sixth day, but was somewhat diminished in the seminal vesicles and uterus. As age advanced there seemed to be no change in the responsivity up to 76 days. The results were based on the weights of the seminal vesicles and on a histological study of them for animals receiving doses of 1, 5, 10, 25, 50, and 100 μg. daily for 6 days.

Antigenic differences between the sperm of different inbred strains of mice, G. D. Snell (*Science, 100 (1944), No. 2595, pp. 272–273*).—Studies of the antigenic properties of sperm samples from mice, dissected out of the vasa deferentia and epididymides from nine different inbred lines, showed that antisperm serum from one family was differentiated from other families by absorption. Results of antisperm properties from a cross of two families point to the presence of a second distinguishing antigen or antigens in the sperm of one of the inbred families.

The role of carotenols in growth and reproduction in the fowl, A. E. SCHUMACHER, H. M. SCOTT, J. S. HUGHES, and W. J. PETERSON. (Kans. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 529–532*).—Carotenoid-free chicks from hens on a carotenoid-free ration died of vitamin A deficiency at 4–5 weeks of age. The chicks grew normally when the ration was supplemented with vitamin A from cod-liver oil or provitamin A. There was no beneficial action on growth or survival from 0.3 mg. luteol or zeaxanthol per chick per day when fed alone or in combination with vitamin A or carotene. Because these carotenols rapidly destroyed vitamin A, possibly by removal of antioxidants, it was necessary to feed them by capsule or by pipette. The fertility of the eggs from 27 pullets free of carotenol, mated with males on carotenoid-free rations, dropped to about 10 percent in over 6 mo. The fertility of the eggs fertilized with semen from 17 males on carotenoid-free rations averaged 82.3 percent. Of these, the eggs fertilized by 9 males gave 100 percent fertility and the lowest fertility of any males in this lot was 50 percent. Evidently carotenols do not possess a vitamin A potency, but the results also demonstrated that carotenols are not essential for reproduction by the male.

Impairment of response to stilbestrol in the oviduct of chicks deficient in L. casei factor ("folic acid"), R. HERTZ and W. H. SEBRELL (*Science, 100 (1944), No. 2596, pp. 293–294*).—Although a marked increase in the oviduct weight of chicks occurred when stilbestrol was administered with folic acid to folic acid-deficient chicks, the increase was only slight from stilbestrol administration in the oviduct weight when no folic acid was given. The oviduct weights of normal control chicks averaged 25 mg. at 21–25 days of age, but when 10γ or 20γ of *Lactobacillus casei* factor was administered daily from birth with 0.5 mg. of stilbestrol on each of the 6 days before autopsy, the oviducts averaged 462 and 450 mg., respectively. When the same doses of stilbestrol were administered but these amounts of folic acid were given during the last 10 days before autopsy, the oviduct weights averaged 184 and 196 mg., respectively. When no folic acid or pantothenic acid was given but 10γ of stilbestrol was furnished daily, the average oviduct weights in response to daily treatments with stilbestrol were 62 and 281 mg. Pantothenic acid-deficient chicks showed a growth failure comparable to that of folic acid-deficient chicks, but there was good oviduct response to stilbestrol. An adequate intake of *L. casei* factors thus seemed essential for normal metabolism of stilbestrol in the chick. The study was conducted with 75 chicks divided into 6 lots for the different treatments.

Incidence of mortality in two strains of Single Comb White Leghorn chickens, R. L. BRYANT and E. P. JOHNSON. (Va. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, p. 521–524*).—Over a 3-yr. period there were consistent differences in the incidence of mortality in two strains of poultry. Among 2,279 chicks in the low-mortality strain there was a 4.34 percent mortality to 8 weeks of age, and 9.91 percent mortality to this age among 1,927 chicks of the high-mortality strain. From 8 to 20 weeks of age the strains showed mortality percentages from different causes of 4.64 and 7.87 percent, respectively. In deaths from all causes after 20 weeks to 525 days of age there were 25.66 and 36.34 percent. Of all the pullets housed, which totaled 1,099 and 1,021 from the low- and high-mortality lines, respectively, 2.99 and 9.06 percent died of some form of leucosis. The differences were highly significant, as well as differences between mortality from specific diseases in individual families.

Length of survival of homozygous creeper fowl embryos, W. Landauer. (Univ. Conn.). (*Science, 100 (1944), No. 2607, pp. 553–554*).—In a study of the effects of temperature of incubation lower than normal on the survival of homozygous creepers, there was no difference in the frequency of late homozygous creeper embryos when the eggs had been incubated at 96° and 99°–100° F. during the first 12 hr. When the lower temperature was extended to the first 24 hr. there was an increase of 170 percent in the frequency of survival, but when the lower temperature of incubation was employed for 48 hr. the greater survival of the creepers disappeared. When the incubation temperature was reduced to 93° for 4 days only 37 percent of the fertile eggs hatched, and when reduced for 7 days a majority of the embryos died during the second week of development. Evidently a prolonged exposure to a reduced developmental rate is harmful. The activity of the homozygous creeper conditions is thus fixed at a younger age than it has been possible to demonstrate by morphological means.

The hatchability of chicken eggs as influenced by diallel crossing, N. F. Waters. (U. S. D. A.). (*Poultry Sci., 23 (1944), No. 6, pp. 495–496*).—Data were based on the hatchability of the developing embryos from 34 sires mated with 51 dams (102 degrees of freedom) divided into 17 sets consisting of 3 dams each, the sets each mated to 2 different sires. The variance analysis showed that the progeny of one sire differed significantly from that of another when both were mated to the same dams. The influence of sires on the hatchability of their progeny thus indicated the heritability of hatchability. No significant influence of the dams on the hatchability of their 2 sets of progeny was apparent.

Genotypic control of feather color pattern as demonstrated by the effects of a sex-linked gene upon the melanophores, B. H. Willier and M. E. Rawles (*Genetics, 29 (1944), No. 4, pp. 309–330, illus. 29*).—Precursor melanophores from the skin ectoderm from the head, the wing bud, or the leg bud, and pure mesoderm from the head from hybrid Rhode Island Red males × Barred Plymouth Rock females were grafted to White Leghorn embryos, both being about the same age. At all ages (66–86-hr. embryos) tested, the donor head-skin ectoderm produced pigment in the wing-down feathers. Of 107 host chicks grafted, 83 were positive and 24 negative. Melanoblasts migrated out from the grafted tissue and produced an area of black-colored down feathers on the host at about the site of grafting. After hatching, the donor-colored down feathers were replaced by contour feathers characteristic of the sex of the donor. The melanophores of the male heterozygous for the sex-linked genes B and S and the autosomal gene E^m produce a nonbarred pigmentation. The specific pigmentation produced by either the male or female melanophore depends on the individual feather germs varying with the position on the body and time of emergence. Sex seemed to have no influence on the pattern produced by grafted melanophores.

"The variations in the character of the nonbarred pigmentation produced appear to depend primarily upon differences in the expressivity of E^m in the melanophores of the various female donors—that is, whether all of the pigmented feathers of a particular host will have either (1) a uniformly black coloration almost without exception or (2) a black-red ('stippled') pattern. From such differences in phenotypic expression it is inferred that the precursor melanophores from the different female donors have different potencies—that is, either a potency for differentiating usually only black melanophores (E^m fully expressed or nearly so) or a potency for differentiating either a red or a black melanophore (expression of E^m sufficiently weakened by modifying factors). In the latter case whether the black or red potency is realized depends apparently upon the physiological properties characteristic of the individual feather germs of the host. Of these properties, the reaction gradient in the epidermal substratum, which differs in value and direction in the different feather germs, appears to play a role in the differentiation of the kind of pigment cell. Growth rate of the feather germ must also be a factor, since in general a high rate favors the formation of black melanophores while a relatively slower rate favors the formation of red melanophores. The presence of *B*, *S*, and E^m are requisite factors in the melanophore of the male hybrid for the formation of black and white barred pattern. *B* provides the melanophore with the special property of behaving rhythmically in pigment production. The rhythmic production of pigment by the melanophores, however, is modified by physiological properties characteristic of the feather germ. Growth rate of the feather germ appears to be one of the modifying factors, since in general a correlation exists between relatively slow rate and distinct barring and between relatively high rate and indistinct barring or its absence. Factors other than growth rate are also involved."

Feed influence on eye color in White Leghorn chickens, N. M. Nelson. (U. S. D. A.). (*Poultry Sci., 23 (1944), No. 6. pp. 541–542*).—Significant differences were found in the eye color of 2 groups of 12 White Leghorn chickens each on high and low pigmented rations. After 141 days the eyes were removed, dried, and extracted. The photometer readings of these extracts were interpreted as indicating a significant influence of feed on eye color.

The correlation between green-grey irises and black feathers in Barred Plymouth Rock pullets, S. J. Slinger and J. J. MacIlraith (*Poultry Sci., 23 (1944), No. 6, pp. 533–537*).—Twenty Ontario breeding flocks of Barred Plymouth Rocks varying in size from 200 to 1,517 birds showed the probability of the coexistence of green-gray irises and black feathers to be much greater than the theoretical probability, thus suggesting a correlation between these conditions and that they are possibly due to the same or linked genes. The relation of the green-gray eye and all-black feathers to lymphomatosis is discussed.

An improved method of obtaining blood from the chicken heart, F. N. Andrews. (Ind. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 542–544, illus. 1*).—Entrance of the heart direct or through a cannula in which the heart has been located and successful extraction of blood maintained the sharp needles in better condition, reduced clotting and mortality, and prevented contamination of the blood sample.

Inherited shortening of the long bones in the turkey, V. S. Asmundson. (Univ. Calif.). (*Jour. Hered., 35 (1944), No. 10, pp. 295–299, illus. 2*).—A short-legged Bronze turkey hen, produced in a commercial flock, when mated to normals produced only normals. From matings of the heterozygotes there were produced in 5 yr. 590 normals and 184 short progeny, thus closely approximating a 3:1 ratio and indicating the character short long bones to be a simple recessive without significant differences in the sexes, although there were slightly more males than females. No linkage between Bronze and short was indicated in the progeny of a heterozygous short Bronze male mated with black hens, but hatchability and viability were so reduced in the shorts that only 3 percent of the short embryos were hatched and raised. Measurements of the long bones showed that the femur, tibia, tarsometatarsus, and humerus of shorts were shorter and thicker than those of normals. The relation of shank length to body weights in homozygous normals and heterozygous shorts was similar.

Cellular antigens in species and species hybrids in ducks, W. H. McGibbon. (Wis. Expt. Sta.). (*Genetics, 29 (1944), No. 5, pp. 407–419*).—Employing immunological technics of Irwin and Cole with pigeons (E. S. R., 84, p. 314), studies were made of the antigens with red cells of the Muscovy and mallard ducks and reciprocal crosses between them. Each species was found to possess specific antigens and the hybrids had most of the antigens specific to each of the parental strains as well as others which were shared by both of the parents. In addition, the hybrids were found by two methods to possess a new or hybrid substance not found in either parent. This substance was not fractionated. The hybrids from each of two matings showed differences in the antigens specific to Muscovy, which was evidently due to the segregation in the heterozygous Muscovy parents. One family of 25 hybrids from a Muscovy male possessed one or the other of two antigens, evidently controlled by one or more genes on a single pair of chromosomes. The study was based on 33 hybrid offspring from 2 Muscovy males and 5 mallard females and 39 hybrids of 3 mallard males and 5 Muscovy females.

X-rays and the reproductive cycle in ring-necked pheasants, L. B. Clark and G. Bump (*Biol. Bul., 87 (1944), No. 2, pp. 134–137, illus. 3*).—Decreased egg production and length of the laying period, with reduced viability of the eggs, followed X-ray treatments of the heads of a few pheasants.

Testicular response to androgen in the light-stimulated starling, J. W. Burger (*Endocrinology, 35 (1944), No. 3, pp. 182–186, illus. 1*).—Testosterone propionate produced no stimulating effects on spermatogenesis in the adult male starling. There was an initial depression in birds during the short-day periods. If spermatogenesis was well advanced under light stimulation, there was no effect from testosterone exogenously administered. The two experiments were conducted from February 17 to March 24 and from March 27 to April 24 when the light from natural sources changed.

FIELD CROPS

[Continuous forage grasses at Fargo] (*North Dakota Sta. Bimo. Bul., 7 (1944), No. 1, p. 26*).—T. E. Stoa reports that bromegrass alone averaged 2.20 tons per acre 1930–43 (omitting 1931), crested wheatgrass 1.98, and reed canarygrass 1.19 compared with bromegrass-alfalfa mixture 2.28 tons and alfalfa alone 1.83 tons.

The spontaneous heating of flaxseed and sunflower seed stored under adiabatic conditions, H. R. Sallans, G. D. Sinclair, and R. K. Larmour (*Canad. Jour. Res., 22 (1944), No. 6, Sect. F, pp. 181–190, illus. 4*).—Storage in an adiabatic thermostat for less than 2 mo. produced heating in flaxseed at 11.4 percent moisture and in sunflower seed at 10.5 percent, suggesting that the commercial limits of 10.5 and 9.5 percent moisture respectively are not too low. Acceleration in the over-all respiration rate of flaxseed and sunflower seed evidently precedes heating, which indicates that heating is caused by active growth of microflora on the grain and, at moisture levels in the order of those required for safe storage, normal embryonic activity is not enough to cause heating. When the relative humidity of the interstitial air in bulk grain exceeds 74 percent, microflora will grow and heating may ensue. Consequently the moisture content of any grain, in equilibrium with air at a relative humidity of 74 percent, will approximate closely the upper limit permissible for admission to "straight" grades. See earlier notes (E. S. R., 91, p. 676).

What alfalfa for Ohio in 1945? C. J. Willard and L. E. Thatcher (*Ohio Sta. Bimo. Bul. 231 (1944), pp. 261–265, illus. 3*).—Behavior of alfalfa varieties in tests indicate locally produced and other variegated alfalfas as first choice and adapted common second if the crop is to be left only 1 or 2 yr. If alfalfa is to stand 3 yr. and difficulty is had with wilt, there is little choice between common and variegated, because the greater wilt-resistance of common alfalfas nearly balances the initial advantage of variegated varieties. Ranger is suggested if wilt is on the farm and alfalfa will stand longer than 3 yr. Buffalo, when seed becomes available, is expected to surpass Ranger for at least the southern two-thirds of Ohio.

"Oklahoma Grimm" proven a fraud by tests at Columbus, C. J. Willard (*Ohio Sta. Bimo. Bul. 231 (1944), pp. 259–260*).—Tests of lots of seed sold in Ohio as Oklahoma Grimm showed that they definitely were not Grimm alfalfa.

Sutter pink beans, F. L. Smith (*California Sta., [1944], pp. 3*).—Seed of Sutter Pink, a new variety of beans derived from Standard Pink × Early Pink are larger and plumper than Early Pink, and bright colored; the vines are intermediate between the parental varieties, and it matures 3 to 7 days later than Early Pink, which it has consistently outyielded. It has the same geographical range as Early Pink and may be planted up to July 20 and harvested about October 15. In the Sacramento Valley and parts of the San Joaquin Valley, where fall rains are a hazard, it is expected to have an important place where earliness, high yields, and high quality of the seed are in demand. A wartime advantage of Sutter Pink is that bean harvest can be completed early in October. Crews, machinery, and trucks are thus released in time for harvesting rice and milo.

Effect of seed treatment on castor beans, R. O. Weibel. (Univ. Ill.). (*Jour. Amer. Soc. Agron., 36 (1944), No. 11, pp. 953–954, illus. 1*).—Treatment of castor-bean seed with two of the newer organic fungicides evidently may be beneficial under some conditions and of little or no advantage under others.

Homologies of the ear and tassel in Zea mays, E. Anderson (*Ann. Missouri Bot. Gard., 31 (1944), No. 4, pp. 325–343, illus. 8*).—Variation in the corn tassel is described character by character, and methods of recording it exactly are outlined. Evidence is presented for ear-tassel correlations, including tassel internode condensation and increase in row number, tassel branch length and ear length, tassel branch pattern and ear shape, and tertiary branches and irregular rowing. In North American corn, the relation between tassel condensation and row number is, in general, close to the equation: Condensation index = row number /10. Tassel condensation reaches highest development in the Mexico City-Toluca area which is also the center for extreme denting. In a discussion of the problem of homologies between tassel and ear, a tentative conclusion is that in so far as the actual forces are concerned both the fused tassel branch hypothesis and the central spike hypothesis may be essentially true. Application of these facts to the genetics of quantitative characters is discussed briefly. With condensation as an example, a distinction is made between multiple factor characters which can be recorded exactly and those which may be analyzed exactly.

Maiz reventador, E. Anderson (*Ann. Missouri Bot. Gard., 31 (1944), No. 4, pp. 301–315, illus. 4*).—Maiz reventador (literally "exploder corn," i.e. popcorn), discovered by I. Kelly in western Mexico, is described as outstandingly slender in cob, leaf, and stem, with tough, strong leaves, stems, and roots. Plant color, when strongly developed, is chiefly along the veins of the leaves rather than between them. It is used locally for confections—pinole and popcorn balls. Widely, if not commonly, grown in western Mexico, its prevalence in out-of-the-way places, as well as close resemblance to the charred remains of prehistoric corn from the region, suggests that there it was once a staple crop. Several of its outstanding characteristics appear desirable in modern corn-breeding programs.

Growth status of the cotton plant as influenced by the supply of nitrogen, C. H. Wadleigh (*Arkansas Sta. Bul. 446 (1944), pp. 138, illus. 27*).—Rowden 2808 cotton plants were grown in sand culture at 8, 25, 75, and 225 p. p. m. levels of N supply, all as nitrates, and designated as series A, B, C, and D, respectively. Some plants were harvested at incipient florescence and others 40 days afterward and the rest were allowed to mature a crop of bolls.

Inception of blooming induced a lowered rate of growth in height. Absolute amount of N absorbed at incipient florescence showed an exponential relationship with amount of N supplied. Green weights of the plants at this time showed very close relationship with absolute amount of protein synthesized.

All nitrogenous components in the several parts of plants harvested when the first blooms were appearing varied with external supply, but a considerable differential existed between plant parts in expressing variability in these nitrogenous constituents. Fibrous roots showed an extreme variability in content of nitrate N. Those of series D plants contained 28 times as much as those of A. Trends in other plant fractions were high but not so extreme. Ammonium N and amides were quite low in these plants, confirming the observation that rapidly growing plants supplied with nitrate may be very low in ammonium N. α-Amino N and soluble organic N showed parallel trends in all tissues. Content was related directly to level of N supply, but main roots showed the largest range in variability of these components and fruiting branches the least. In all series, the soluble organic N content was higher in fruiting branches than in any other plant part. Nitrogenous materials were accumulating in fruiting branches at this time regardless of potential reserves. The wide range in soluble organic N in main roots was one of the better indexes of potential productivity of these plants. Carbohydrates tended to follow an inverse trend with nutrition. Except in A plants, carbohydrate reserves were relatively low. Concomitant with the wide latitude of soluble organic N observed in main roots, sucrose also showed a similar wide latitude but with the converse trend. Starch accumulation in leaves and stems appeared to be a good index of low potential production.

Trends of the several nitrogenous and carbohydrate components in vegetative parts of plants harvested 40 days after incipient florescence were similar to those observed on the plants harvested earlier, although the content of nitrogenous materials tended to be lower at the latter date. A wide latitude was noted in content of soluble N in the hulls. Hulls might act as a temporary N storage reservoir prior to translocation into developing ovules. Plants yielding poorest (A) were much the highest in carbohydrate reserves at this second sampling date also. Carbohydrates tended to accumulate in leaves and lower stems.

Plants maturing a crop of bolls averaged 27.0, 57.3, 119.8, and 143.0 gm. of seed cotton per plant for series A, B, C, and D, respectively. Fruiting charts revealed that, after a plant had set bolls enough to deplete its nitrogenous reserves, all young bolls subsequently formed abscised; and, soon thereafter, young squares abscised and terminal buds of the fruiting branches aborted. There was little relation between percentage of abscission and treatment. Abscission appears to act as a "safety valve," in that all bolls are shed which could not be developed adequately at the obtaining level of plant metabolism. Carbohydrate reserves seemed to be actually limiting for boll setting on plants with the highest level of N nutrition. No significant difference was noted in the average number of seeds produced per boll between treatments, although on A and B plants (low N) there was a marked decrease in average number of seeds per boll with advance of fruiting season and the converse trend on C and D (high N) plants. While there was no significant difference on average number of aborted embryos or motes per boll between treatments, seeds and motes per boll showed the expected inverse trends. As specific food reserves in the plant become limiting, a corresponding increase evidently results in the abortion of initiated embryos in the young bolls.

Boll size, average weight of individual seeds, and length of lint (slightly) tended to rise with increase in level of N nutrition while lint percentage tended to decrease. Protein content of seeds increased markedly with treatments conducive to increasing nitrogenous reserves within the plant. Seeds of A plants contained 17.6 percent protein and of D plants 27.0. Oil content decreased with a lowering in carbohydrate reserves as conditioned by N nutrition, the seeds from A plants averaging 29.2 percent oil and D plants 24.1. The trend for gossypol content was similar to that for oil.

A diagram shows interrelationships of certain major biochemical equilibria in the cotton plant as they relate the quality and quantity of plant product. It is considered to be economically advantageous to maintain cotton at a high level of N metabolism prior to the fruiting period, apparently because the high requirements of food reserves for developing bolls compete with roots for these reserves and thereby limit root performance as to nutrient uptake even though nutrient be plentifully available during boll maturation.

A list of 114 citations to the literature is appended.

Effect of nitrogen and phosphorus on the yield and root rot response of early and late varieties of cotton, L. M. BLANK. (U. S. D. A. and Tex. Expt. Sta.). (*Jour. Amer. Soc. Agron., 36 (1944), No. 11, pp. 875–888, illus. 1*).—Effects of N and P fertilizers in combination with early and late maturing cotton varieties upon seed cotton yields and incidence of root rot were studied 1940–42 near Brenham on Houston black clay and near Caldwell on Crockett clay loam. Mean effects of N were to decrease the amount of disease by a significant or highly significant margin in 2 yr. at each location, and yields were increased significantly in all years at both locations. P had no appreciable effect upon yield or disease at Brenham, while at Caldwell both were increased in 2 yr. Early varieties as a group were as susceptible to disease as the later cottons, yet they outyielded the latter by a highly significant margin in all years at Caldwell and in 2 yr. at Brenham. See early notes by Reynolds and Rea (E. S. R., 71, p. 468) and by Adams et al. (E. S. R., 84, p. 611).

The Menominee potato: A new variety resistant to common scab and late blight, E. J. WHEELER, F. J. STEVENSON, and H. C. MOORE. (Mich. Expt. Sta. Coop. U. S. D. A.). (*Amer. Potato Jour., 21 (1944), No. 11, pp. 305–311*).—Menominee, a selection from Richter Jubel × Seedling 44537 (a russeted mutation in Chippewa × Katahdin) and first grown at Presque Isle, Maine, is described as highly resistant to scab and moderately so to late blight. Tests in Michigan showed that this late-maturing variety, if planted early, will produce relatively high yields of tubers of good cooking quality. The tubers do not cling to the vines when harvested before the plants are mature as do those of Russet Rural and Sebago. Menominee has consistently outyielded Chippewa, Russet Rural, and Sebago in bushels of U. S. No. 1 per acre at Lake City and Rogers City, Mich. Menominee is being distributed to growers in the late potato-growing sections where U. S. No. 1 potatoes of the old commercial varieties can no longer be produced because of common scab. Most of the 2,800 bu. of seed of this variety produced in 1943 was to be grown for increase in 1944.

Resin-rubber from Canadian grown plants, I, II (*Canad. Jour. Res., 22 (1944), No. 6, Sect. F, pp. 199–207, illus. 2; pp. 208–220, illus. 3*).

I. *Variation in selected genera,* R. W. Watson and N. H. Grace.—Common milkweed was selected from the most promising native genera as the only species with a resin-rubber content high enough to warrant extraction studies. Rubber is concentrated in the leaves. Drying milkweed under glass in air and full daylight at temperatures up to 60° C. has not reduced the rubber content. Concentrates are produced by fermentative decomposition. The leaf rubber content gradually increases during the growing season, with a maximum of about 3.5 percent in late September in the Ottawa district.

II. *Method of extraction from the common milkweed, Asclepias syriaca L.,* N. H. Grace, R. W. Watson and J. Klassen.—Resin-rubber gum containing about 40 percent resin, rubber 35, and residue insoluble in either acetone or benzene 25 percent, has been extracted from milkweed leaves by a method involving cooking leaves in dilute alkali, washing until the pH is reduced to about 9.5, and pebble milling to effect agglomeration. Sodium hydroxide solution (1.5 percent) boiling at atmospheric pressure has been used with cooking periods of from 2.5 to 3 hr. Gum yields about 8 percent of the weight of dried leaves have been obtained. Resin-rubber gums also have been obtained by this method from stalks and seed pod hulls of milkweed, and similar materials have been extracted from a number of other plants.

Soybean trials in Wyoming, W. L. QUAYLE (*Wyoming Sta. Bul. 267* (*1944*), *pp. 12*).—Seed and forage yields obtained in tests at several substations showed that at high elevations, the soybean varieties tried are not well adapted to the cool temperatures and short growing seasons. Under conditions like those at Torrington varieties made much better yields, but the 1940–43 average of Great Northern beans at Torrington, 42.8 bu. per acre, was 146 percent greater than the highest average yield of soybeans. Although the cost of production per acre is about the same, the average selling price of soybeans in the United States, 1931–43, was less than half that for edible beans. Under the conditions, higher yielding varieties must develop before growing soybeans as a commercial crop is warranted in this part of the State.

A study of the morphological nature and physiological functions of the awns of winter wheat, E. C. MILLER, H. G. GAUCH, and G. A. GRIES (*Kansas Sta. Tech. Bul. 57* (*1944*), *pp. 82, illus. 22*).—Plants of Kanred, Tenmarq, Early Blackhull, Turkey, Kanred × Hard Federation, Kawvale, and Fulcaster awned or bearded red winter wheats, grown in rows at Manhattan, Kans., 1935–38, were totally deawned, which involved severance with small pointed scissors of all awns of the head and beaks of the outer glumes. Others were partially deawned, i.e., with complete severance of one-half of the awns of the head. Awns were removed 4 to 7 days before, at blooming, and 7 to 14 days after.

Total and partial deawning in general decreased the weight of grain as determined from study of 100 heads. Partial deawning as a rule decreased weight of grain by about one-half that of the totally deawned. Decrease in weight of grain usually was greatest when heads were deawned before blooming. Effects of deawning tended to be less with lapse of time following deawning. Total and partial deawning generally decreased the weight of 1,000 kernels. This decrease represented about 50 to 80 percent of the decrease in yield due to deawning. Number of kernels produced by 100 heads was reduced by both types of deawning, with the more striking reductions in heads totally deawned. Deawning before blooming caused greatest reduction in number of kernels, whereas that two weeks after blooming had little or no influence on this character. No percentage increase in ash of grain followed either type of deawning.

Effects of partial deawning were also studied with Turkey and Kawvale in relation to changes in the nature of grain produced on the same head. There was always a decrease in weight of grain produced by the deawned portion of 100 heads and usually of 1,000 kernels from deawned portions of the head, as compared to the intact portions of the same heads. Decreases for 100 heads ranging from 46.48 to 4.10 percent, and for weight of 1,000 kernels, 11.15 to 2.33 percent (weighted averages), were greater the earlier heads were deawned. Fewer kernels were produced in the deawned portions than in the intact portions of the same heads. In general, number of kernels produced by deawned spikelets of Turkey was 2.5 times greater than by deawned spikelets of Kawvale, and this decrease became greater the earlier the heads were deawned. In most cases weights of glumes in both varieties were increased by both total and partial deawning. Ash content of glumes usually increased slightly as a result of deawning. Weight of the awns was not increased in the partial deawning of these heads at the deawning stages. Percentage of ash in the awns on the deawned portion of the heads always exceeded that in the controls. Deawning resulted in most cases in increase in weight of rachises and in the weight of their ash.

Response of wheat varieties to applications of superphosphate fertilizer, L. P. REITZ and H. E. MYERS. (Kans. Expt. Sta.). (*Jour. Amer. Soc. Agron.,* *36 (1944), No. 11, pp. 928–936)*.—Responses of Turkey, Tenmarq, and Quivira winter wheats 1931–38 and Kanred × Hard Federation 1936–38 to applications of superphosphate were compared on Geary silt loam at Manhattan, Kans. Phosphate applications resulted in increased yields of grain and straw, slightly higher test weight, greater percentage of yellow berry grains, reduced protein content of grain, and hastened maturity. The varieties gave significantly different yields of grain. Variety-fertilizer interaction for grain yield was significant at the 1-percent level in 1932 and at the 20-percent level in 1931 and 1935, but not significant for the entire period. Varieties of similar adaptation tend to respond in similar manner to applications of phosphate fertilizer.

Tensile strength of yucca fibers, C. W. Botkin and L. B. Shires (*New Mexico Sta. Bul. 316 (1944), pp. 30, illus. 6*).—Further studies on native fiber plants (E. S. R., 89, p. 204) dealt with strength of fiber from all abundant *Yucca* species and significant effects of extraction methods or leaf condition on fiber strength.

Yuccas were grouped as flexible-leaved, represented most abundantly by *Y. glauca and Y. elata,* and rigid or bayonet-leaved which include *Y. baccata, Y. torreyi, Y. schidigera,* and *Y. faxoniana* among abundant species. Tensile strengths in kilometers of fibers obtained from these respective species averaged 44.7, 47.5, 60.2, 61.1, 50.4, and 54.0. These strengths compare favorably with values obtained for the best commercial fibers: Palma istle 43.1, African sisal 43.0, jute 33.2, Wisconsin hemp 47.3, and Manila (abacá) 62.0 km. Yucca fiber was weakened somewhat by autoclaving at higher temperatures and by use of sodium carbonate and bisulfites of sodium and calcium at concentrations and temperatures high enough to be very effective in softening the leaves. Injury appeared to increase with ease of decortication of the leaves. Yucca fibers may be decorticated without weakening, however, by autoclaving at lower temperatures without aid of chemical reagents. Fiber is separated more readily from flexible leaves than from bayonet leaves, and extracted more easily from green than from dry leaves. Clean yucca fibers are white and lustrous. Flexible-leaf fiber, slightly finer and softer than bayonet-leaf fiber, is suited to making twine, burlap, rope, and special kinds of hard-fiber paper. Bayonet fiber is stiffer and stronger and suitable for strong rope and twine, soft brushes, and other hard-fiber uses.

HORTICULTURE

Specific gravity determination as an aid in research, W. C. Kelly and O. Smith. (Cornell Univ.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 329–333*).—Although many horticultural products are adaptable to rapid specific gravity determinations, relatively few workers have used this technic. Relations between specific gravity, quality, and dry weight have been reported with the few products studied. These determinations are valuable in selecting high quality products, in selecting uniform samples, and in comparing the percentage dry weight of different lots in field and storage experiments. The specific gravity of potatoes has been studied extensively and has proved to be a valuable research tool in the study of cooking quality.

Misconceptions relative to the method of foliar diagnosis, W. Thomas and W. B. Mack. (Pa. State Col.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 355–361)*.—The authors discuss the conceptions of various agricultural investigators with respect to the diagnosis of the nutrient requirements of crop plants by means of leaf analyses. Objections to the method of foliar diagnosis are answered, and the validity of the fundamental concepts upon which this method is based is reaffirmed.

Key to common vegetables based on vegetative characters, P. G. Smith and J. H. MacGillivray. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944),* *pp. 334–338)*.—A key found useful in the classification of cultivated vegetables is presented.

Grafting in the Solanaceae, R. F. DAWSON (*Gard. Chron. Amer., 48 (1944), No. 8, pp. 235, 242, illus. 2*).—"Because of the great ease with which graft unions develop in the Solanaceae the stock-scion relationships of this group have been studied in some detail in the Princeton [University] greenhouses. Some of the results that have been obtained seem sufficiently interesting and suggestive to warrant a brief description for the benefit of gardeners in general."

Nitrogen requirements on different groups of vegetables, L. M. WARE and W. A. JOHNSON. (Ala. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 343–345*).—The yield of each type of vegetable grown on soil of the Norfolk series increased with each successively larger amount of nitrogen applied up to 120 lb. per acre, the maximum rate used. However, the relative yields of the various vegetables grown differed materially at the intermediate rates of nitrogen application. For example, the relative yield of white potatoes and sweetpotatoes at the 30 lb. of nitrogen rate was 85.9 percent of the yield with 120 lb. of nitrogen as compared with 67.7 percent for other root crops, 55.9 percent for pod-bearing crops, and 58.9 percent for leafy crops. The nitrogen responses on Decatur and Hartsell soils are discussed somewhat more briefly because of limited data.

Studies in the minor element nutrition of vegetable crop plants.—I, The interrelation of nitrogen, phosphorus, potash, and boron in the growth of rutabagas, R. H. WHITE-STEVENS and P. H. WESSELS. (Cornell Univ.). (*Jour. Amer. Soc. Agron., 36 (1944), No. 11, pp. 903–921*).—Instances of boron (B) deficiency were noted under field conditions even when recommended applications of borax had been made. Different degrees of B deficiency were observed on susceptible crops, associated with and dependent apparently on N, P, and K fertility levels employed. N, P, and B were found to have positive main effects on growth in greenhouse experiments with rutabagas involving two levels each of N, P, K, and B. K had no main effect, but showed a positive interaction with N. B also showed a positive interaction with N. P showed a negative interaction with B. N × P × B was also a negative interaction in relation to growth. N, P, and B all promoted root growth to a greater extent than foliage growth. K and B each amplified the N effect. B, N, and P, in order given, all showed significant controlling main effects on the incidence of B-deficiency symptoms in the rutabaga. K showed a significant deleterious effect in this regard. N interacted with P to enhance the deficiency and with K and B to reduce it. P interacted with K and B to reduce deficiency. N, P, and K mutually enhanced deficiency symptoms, but P, K, and B naturally reduced them.

The effect of "split applications" of nitrogen and phosphorus on the yields of tomatoes and large seeded lima beans, E. M. EMMERT. (Ky. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 433–440*).—With tomatoes, application of 500 lb. of 20 percent superphosphate in the holes at time of setting the plants and again in four holes close to the plants, before fruit set, gave the best results. For lima beans, double drilling these same amounts at the start and before pod set gave considerably higher results than were recorded with tomatoes receiving comparable treatment. The effect of phosphorus applied in starter solutions was significantly less than in most of the other methods of application. With tomatoes, nitrogen did not show as definite results from split applications as did phosphorus. Nitrogen applications before the fruit set gave decreases and no significant increases. The only highly significant increase for nitrogen on lima beans was obtained with split applications.

The effect of sawdust on the production of tomatoes and fall potatoes and on certain soil factors affecting plant growth, W. A. JOHNSON. (Ala. Expt. Sta.).

(*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 407–412*).—Using pine sawdust 10 yr. or more of age, the author found that on a Chesterfield sandy loam soil such material can be incorporated with the soil without harmful effects if sufficient nitrogen is used to offset the resulting nitrogen depression. The effects of sawdust on yields depended on three factors (1) whether sawdust was used as a mulch or was incorporated in the soil, (2) the lapse of time following sawdust application, and (3) the amount of nitrogen applied. As a surface mulch, sawdust increased the yields the first year, caused a slight depression of nitrates the first year and a greater depression the second, increased the moisture in the soil, and resulted in a more uniform soil temperature. When incorporated in the soil, the nitrates were depressed greatly during the first 18 mo., after which they began to accumulate. The incorporated sawdust increased soil moisture and loosened the texture of the soil.

"Hormone" sprays for snap beans, A. E. Murneek, S. H. Wittwer, and D. D. Hemphill. (Mo. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 428–432*).—Snap beans were sprayed with two growth-promoting substances, naphthaleneacetamide and naphthoxyacetic, at various concentrations. The relation of weather to the activity of the materials was shown in the fact that the highest increase in yield from hormone sprays was obtained in the summer of 1941 during a period of high temperature, whereas in the cool summer of 1942 there was an actual decrease in yield from spraying. Spring and fall crops of beans grown during cool weather may be harmed by these sprays. Of the concentrations used the more dilute, particularly the 5 p. p. m., were more efficient. It is believed that the beneficial effects, when occurring, are due chiefly to a direct stimulation in growth of the pods and an increase in the clorophyll content of the leaves. Fertilization and development of the embryo were apparently not affected by the materials. Because they did not overcome the unfavorable effects of weather and because of their cost, their use is not as yet recommended for general practice.

The use of sprays to set greenhouse tomatoes, R. H. Roberts and B. E. Struckmeyer. (Wis. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 417–427, illus. 9*).—Wetting the blossoms with a water solution of β-naphthoxy acetic acid or of 2, 4-dichlorophenoxy propionic acid in proper concentrations proved a practical method of setting the fruit on the lower clusters on the winter-grown tomatoes. Such treatments did not prevent the dropping of yellowish blossoms with inadequate nutrition, but was highly effective on green and persistent type flowers. Spraying very young blossoms resulted in smaller fruits. One thorough spraying of clusters of well advanced blooms gave 5–7 tomatoes of relatively uniform size. Fruits obtained by spraying were comparable to those obtained by pollination except for a greenness around the placental area. The fruits set with spray were harder to pick. The heavy drain induced by a full set of fruit must be offset by better cultural and fertilizer practices.

Further results with sprays and dusts in controlling the preharvest drop of apples, L. Southwick. (Mass. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 109–110*).—Continuing the general study (E. S. R., 90, p. 52), the author found that stop-drop dusts applied early in the morning while dew was still on the foliage and fruit were effective in decreasing the preharvest dropping of McIntosh apples. Somewhat better results were obtained with double-strength dusts and sprays and with two applications of dust or spray.

The effect of some new spray materials on the rate of apparent photosynthesis of apple leaves, S. A. Pieniazek and E. P. Christopher. (R. I. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 105–106*).—Where Fermate, combined with fresh hydrated lime at the rate of 1.5 lb. of Fermate and of 1.5 lb. of hydrated lime per 100 gal. of water, was applied to Baldwin apple leaves, there was no visible injury at moderately low temperatures and only a slight reduction in carbon dioxide assimilation. Even at higher temperatures, injury was much less than with lime-sulfur. Tests were made also with a material known as Q_1 with even less injury and less effects on carbon dioxide assimilation.

Lime as a "safener" in lime sulphur and lead arsenate sprays, E. P. Christopher, S. A. Pieniazek, and C. Jennings. (R. I. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 101–104*).—Studies with leaves of mature Baldwin and McIntosh apple trees failed to support the concept that lime may be used as a "safener" in combination sprays of lime-sulfur and arsenate of lead. Baldwin foliage proved more susceptible to injury than did McIntosh. In greenhouse trials, a spray of lime alone had no effect on the carbon dioxide assimilation of apple leaves. Where lime was added to a lime-sulfur and lead arsenate spray, carbon dioxide assimilation was little affected or even somewhat further reduced.

The elimination from the atmosphere of ethylene evolved by apples, R. M. Smock. (Cornell Univ.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 134–140, illus. 3*).—Brominated activated carbon was the most successful agent tested for the removal of naturally evolved ethylene from the storage chamber. Bromination appeared necessary because plain activated carbon was not effective at the high relative humidities that are required in keeping apples. Although oiled paper was of some value in retarding softening induced by ripe apple vapors, it did not approach the effectiveness of the brominated carbon. Wraps impregnated with ammoniated copper fluoride were of no value and the use of ozone was of a dubious value, although in high concentrations it was of some benefit by combining with the ethylene.

The relation of leaf area per plum to physical properties and chemical composition, E. L. Overholser, C. L. Bedford, and A. L. Kenworthy. (Wash. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 94–98*).—Observations on Santa Rosa and Vacaville plums showed a progressive increase in weight, size, and color of the fruit as the number of leaves per ringed branch increased from 1 to 8 leaves. It was evident that, when less than 8 leaves were available to each fruit, inadequate material was elaborated to meet the needs of both the developing fruits and potential flower buds for the succeeding crop. In the succeeding year, when leaf : fruit ratios as high as 32 : 1 were established, the Vacaville plums continued to gain in size up to 32 leaves per fruit. On the other hand, the Santa Rosa plums showed no benefit beyond 16 leaves per plum. In the first season with 8 leaves as a maximum, there was recorded an increase in the percentage of dry matter, reducing sugars, and total sugars as the number of leaves per fruit increased. In the second year with 32 leaves per plum, reducing sugars, sucrose, and total sugars on a percentage basis tended to increase in the fruits in the Santa Rosa variety up to the maximum number of leaves. The trends were not as consistent in the Vacaville variety. The acidity of the Vacaville plum tended to decrease with increase in leaves, while that of the Santa Rosa was not consistently affected by leaf : fruit ratio.

Strawberry variety performance in Ohio, W. P. Judkins (*Ohio Sta. Bimo. Bul. 231 (1944), pp. 266–267*).—Based largely on the results of trials at Wooster, a large number of varieties are rated as to their merit with notations as to time of maturity, yielding capacity, size of fruits, firmness of fruit, and quality. The four most important commercial varieties were Shelton, Premier, Catskill, and Green Mountain, the last an everbearer.

The effect of various treatments and methods of handling upon rooting of muscadine grape cuttings, F. F. Cowart and E. F. Savage. (Ga. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 312–314*).—Treatment of muscadine grape cuttings with various growth-promoting substances, either in powdered or solution form, did not result in any material increase in the percentage of successful rooting. Root formation was apparently stimulated to a slight extent in some instances, but the increase in the actual number of cuttings to form roots was small. As to type of cutting wood, no difference was evident in the number of cuttings to form roots irrespective of the position of the parental shoot. Modifications in the rooting medium had no significant effect on the percentage of rooting. Storage of cuttings prior to setting directly in the rooting medium had no beneficial effect on percentage of successful rooting.

Fertilizing desert grapefruit, A. H. Finch. (Univ. Ariz.). (*Calif. Citrog., 30 (1944), No. 2, pp. 34–35, illus. 1*).—The leaf nitrogen in full-grown grapefruit leaves ranges from a minimum of about 1.2 to a maximum of about 2.2 percent of the dry weight of the leaf. A high level of leaf nitrogen in the winter and spring, declining to a low level in summer and fall, is indicative of a condition of orchard fertility favorable to high yields of good quality fruits. The use of leaf analysis in connection with a chart showing desirable seasonal levels of leaf nitrogen is offered as a key to the proper fertilization of Arizona grapefruit orchards.

Response of Deglet Noor date palms to irrigation on a deep sandy soil, W. Reuther. (U. S. D. A.). (*Date Growers' Inst. Rpt., 21 (1944), pp. 16–19, illus. 2*).—Young Deglet Noor date palms growing in sandy soil with no underlying silty soil until a depth of 9–16 ft. was reached made only about one-half the development of nearby palms located where silty soil was only a short distance from the surface. When the palms in the deep sand were supplied with a steady supply of water in addition to the regular irrigation there was a marked increase in vigor and number of inflorescences produced irrespective of whether nutrient materials were added with the water. The data suggested that insufficient water rather than inadequate soil fertility is the primary factor for the low vigor of date palms in deep sandy soils. The additional water should be particularly valuable to young nonbearing palms whose roots have not reached the deep lying silt layer. Apparently the rate of moisture loss by the palms is often so great that sandy soil cannot transmit water to the roots rapidly enough to supply the requirements for maximum vigor.

Glazing and hydrating dates, G. L. Rygg. (U. S. D. A.). (*Date Growers' Inst. Rpt., 21 (1944), pp. 7–10*).—Deglet Noor dates of No. 1 dry and waxy-tip grades gained in weight to the extent of 7–9 percent when held for 2 days in an atmosphere maintained at 117° F. and 90 percent relative humidity. The treatment softened the fruit enough to make it acceptable commercially, but did not impart stickiness to the surface. The dull finish resulting from the treatment can be remedied by exposing the dates to a temperature of 266°–284° for 5 min. while the air is stirred vigorously. This treatment melts the natural wax and imparts a luster to the skin.

The effect of certain wax emulsions on the incidence of shrivel and on the respiration and development of date fruits, W. Reuther and C. L. Crawford. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 172–182, illus. 3*).—Observations on dates taken from bunches, half of each of which was sprayed in different schedules with various wax emulsions while yet attached to the palms, showed that in general those emulsions in concentrations greater than 1 percent of solids reduced markedly the incidence of shrivel. The advantage was more than offset by the abnormally dark color of the ripened fruit, the undesirable flavor, and the loss in yield due to decay and drop. Certain wax emulsions having 1 percent or less of solids, when applied late, showed some promise for commercial control of shrivel.

The stronger wax emulsions did not markedly influence fruit respiration, but did reduce the dry weight of mature fruit without reducing fruit volume and also delayed ripening to some degree.

Specific gravity as a criterion of filling in the pecan nut, B. G. Sitton. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 89–93, illus. 2*).—The need is set forth for a simple and reasonably accurate measurement of the degree of filling of pecan nuts. Studies with selected Stuart and Schley nuts showed that the relationship between the specific gravity and the weight of the whole nut, the weight of the kernel, the weight of oil, the percentage of kernel, and the percentage of oil are all good indicators of the degree of filling. Specific gravity provides an integration of the weight, the size, and the shape, and is thus a measure that may be used to estimate filling in nuts of different sizes and of different varieties. Specific gravity proved to be correlated directly with the quality and flavor of the nuts. In Schley and Stuart, nuts having a specific gravity of 0.85 or higher were of high quality and excellent flavor.

Vegetable growth on Persian walnut trees associated with nut production, C. E. Schuster. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 85–88*).—Studies in two Persian walnut orchards, one located on a relatively poor hill soil and the other on a river-bottom soil, showed a much higher percentage of short shoots (12.9 cm. or less) in the trees on the poorer soil. Of the total crop of nuts borne on trees on poor and good soil, 72.9 and 50.0 percent, respectively, were produced on these short shoots. Observations on longevity of shoots showed the highest mortality among shoots 5 cm. or less in length and also among those that were not producing nuts. On Parisienne walnut trees for every 100 lb. of nuts matured during the season there were produced 21 lb. of new shoots, 25 lb. of hull, and 120 lb. of leaves. For every nut averaging 8.35 gm. there were 1.73 gm. of current shoot growth, 2.08 gm. of hulls and 10.09 gm. of leaves. From observations on a felled tree the author computed that on a basis of 100 lb. of nuts, there would be produced 214 lb. of wood, 25 lb. of hulls, and 120 lb. of leaves.

The initiation and development of foliar and floral organs in the tulip, J. E. Sass. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci., 18 (1944), No. 4, pp. 447–456, illus. 9*).—The observations made in a study of the seasonal sequence and histology of leaf and flower initiation in the tulip are reported.

A study of dormancy and germination of seeds of Cercis canadensis, M. Afanasiev. (Okla. Expt. Sta.). (*Jour. Agr. Res. [U. S.], 69 (1944), No. 10, pp. 405–420, illus. 4*).—Because of the impermeability of the seed coat to water and the protracted dormancy of the embryo, redbud seeds under natural conditions usually remain dormant for some years on the soil before germinating. Seed coats were rendered permeable by treatment with sulfuric acid, hot water, or mechanical scarification. Seeds held for 15 mo. required a lengthening of the sulfuric acid treatment. Afterripening of the embryo was hastened by stratifying acid-treated seeds. Holding afterripened seeds in pure oxygen for 24 or 48 hr. increased markedly the rate of germination. The optimum germination of afterripened seeds occurred at 70° F., with some germination at a temperature as low at 33°. At 100° germination was slow and the resulting seedlings were weak. Drying of afterripened seed tended to reduce germinability. Vitamin B_1 had no appreciable benefit on afterripening or germination. Catalase activity increased during the progress of afterripening.

FORESTRY

Our forests: What they are and what they mean to us, C. E. Randall and M. F. Heisley (*U. S. Dept. Agr., Misc. Pub. 162, rev. (1944), pp. 38, illus. 18*).—This revision, the original of which was noted earlier (E. S. R., 70, p. 190), contains information as to forests and how they grow, forest regions of the

United States, function of the forests in conserving water and soil, supplying lumber, fuel, and many products, fire control, insect and plant diseases, forest administration, and related topics.

The forest resources of Chile, P. A. Briegleb and I. T. Haig. (U. S. D. A. et al.). (*U. S. Dept. Agr., Agr. in Americas, 4* (*1944*), *No. 12, pp. 223–226, 234–235, illus. 5*).—Information is offered on the distribution and extent of Chilean forests, their approximate content of usable lumber, species, facilities for handling the forests, their output, etc.

The windbreak as a farm asset, C. G. Bates (*U. S. Dept. Agr., Farmers' Bul. 1405, rev.* (*1944*), *pp. 22+, illus. 9*).—This revision (E. S. R., 51, p. 146) contains an explanation of the general principles of protection obtained from planted windbreaks, the good and bad effects that may be expected, desirable species, management, etc.

Effects of fire on gum yields of longleaf and slash pines, V. L. Harper (*U. S. Dept. Agr. Cir. 710* (*1944*), *pp. 42, illus. 16*).—A study of the effects of different types of burning on the gum yield of longleaf and slash pines growing on the Olustee Experimental Forest, Fla., indicated that a light surface fire may be actually slightly beneficial, but that heavier fires are distinctly harmful. In the case of longleaf pine, a light surface fire increased yield of gum by about 4 percent the first year and had no appreciable effect on yield the second year. Similar effects could be expected with slash pine. With both species, heat treatments that killed needles decreased yields during the first succeeding year by as much as 19 percent, and mild crown fires reduced yields as much as 64 percent. Defoliation in late spring caused about twice as much reduction in yield as did defoliation in early spring. In the second year yields were approximately normal on all trees. Stem scorching caused no serious reduction in yield except in the case of unusually heavy crown fires. The advisability of deferring turpentining for 1 yr. after a mild crown fire and for 2 yr. after a heavy crown fire is suggested. Periodic burning with light surface fires is a precautionary measure against severe fires resulting from an accumulation of grass, vines, and underbrush.

Christmas tree test, R. B. Paton (*Ohio Sta. Bimo. Bul. 231* (*1944*), *pp. 257–259*).—Norway spruce brought into a room held at 68°–70° F. began to drop their needles in less than 14 days in nearly all cases, while comparable trees with their cut ends in water retained their needles an average of 21.9 days. Shellac treatment of the butts had no benefit on durability.

The chemical softening of wood for microtome sectioning, W. M. Harlow (*N. Y. State Col. Forestry, Syracuse Univ., Tech. Pub. 63* (*1944*), *pp. 16, illus. 2*).—The author brings together descriptions of various methods as gleaned from the literature and adds the results of certain experiments conducted by himself.

DISEASES OF PLANTS

[Abstracts of papers accepted for presentation at the thirty-sixth annual meeting of the American Phytopathological Society, Cincinnati, Ohio, December 9 to 11, 1944] (*Phytopathology, 34* (*1944*), *No. 12, pp. 997–1014*).—Included are papers—in large part from State experiment stations—by various authors on plant diseases and their control. Those dealing with specific hosts are as follows: Apple—spray boom for ground spraying, Isothan Q15 against scab, Puratized N5D, Fermate, and Methasan against scab and bitter rot, and soil treatments v. replant survival in *Xylaria*-infested soils. Cabbage—benzene vapor against mildew, Ca-K balance in relation to club root, and breeding for yellows and mosaic resistance and high ascorbic acid content. Cereals and grasses—Traveler oats grain yield v. size of crown rust pustules; wheat stem rust in relation to temperature and nutrients, light v.

infection types by physiological races on resistant and susceptible varieties, and wheat improvement in relation to physiological races; *Xanthomonas vesicatoria* overwintering on wheat roots; root rots v. date, rate, and depth of planting spring wheat; *X. translucens* host relations, and seed and seedling infection of barley, wheat, and *Bromus inermis;* pyrenophora leaf spot of *B. inermis; Ustilago striaeformis* chlamydospore afterripening, and testing bluegrass for resistance; and ontogenetic characteristics of *U. linearis* f. *hordei.* Cherry—eradicant sprays for *Sclerotinia laxa,* fungicide and insecticide deposition on leaves, leaf spot control by high Ca v. high Mg-lime bordeaux, virus complex, and hosts of necrotic ring spot and yellows of sour cherries. Chrysanthemum—soil treatment for foliar nematode. Cotton—environal factors in boll shedding. Elm—bacterial wetwood, factors in Dutch elm disease development, and immunization against *Verticillium albo-atrum.* Flax—seedling blight and root rot in Washington State. Grape—black rot eradication by Elgetol, and phylogenetic relationships of nine known leafhopper vectors of Pierce's disease. Guar—lethal virus. Hops—twine treatment for downy mildew. Peas—anthracnose, treatment for *Aschochyta* on seed, and gene for resistance to near-wilt. Peach—X disease transmission to herbaceous hosts, and its chemotherapy. Potato—DDT tests, leafhopper and early blight control by zinc dimethyl dithiocarbamate, hormone treatment against sprouting losses, bacterial soft rot v. temperature, fusarium seed piece decay, disease resembling fusarium wilt, pythium tuber rot and wilt, pythiaceous stem-end rot, scab in relation to Ca-K balance, net necrosis and "stem-end browning" v. storage temperature, resistance to leaf roll, viruses of mottle and punctate necrosis identical, and nature and cause of purple-top wilt. Soybean—dusting for bacterial pustule control. Sugar beet—seedling diseases in Ohio. Tobacco—stimulation by peanut-hull meal in seedbed, relations of variety and inheritance to water-soaking, seedbed treatments, and blue mold eradication. Tomato—rhizopus stem blight, alternaria blight v. maturity, early blight and anthracnose control by zinc dimethyl dithiocarbamate, 10-State control test against anthracnose, defoliation disease control by 2,3-dichloro-1,4-naphthoquinone, predisposition to fusarium wilt, and fusarium wilt fruit invasion and seed carriage.

Other abstracts deal with bacterial invasion via stomata; tissue cultures as influenced by crown gall bacterial metabolites and tissue extracts and by culture media; preemergence damping-off severity in relation to growth rates of host and pathogen; basidiospore cultures of *Rhizoctonia solani* compared; electrophoretic studies of plant viruses, and a rapid method of mechanical transmission; and the influence of water on host plant predisposition to diseases.

Special studies on fungicides deal with the following: Assay by slide germination, by greenhouse weathering, and by greenhouse snapdragon rust technics; a new dust with adherence; pyridine, quinoline, and nicotinium derivatives as fungicides; compatibility of organic fungicides with summer oil; new organic fungicides for orchard fruits; the Zn salt of dimethyl dithiocarbamic acid (Methasan and Zincate) for vegetables; and the fungicidal action of reagents for amino acids, amines, aldehydes, and other reactive cell constituents.

The Plant Disease Reporter, [October 15 and 22 and November 1 and 7, 1944] (*U. S. Dept. Agr., Plant Disease Rptr., 28 (1944), Nos. 33, pp. 995–1026, illus. 2; 34, pp. 1027–1053; 35, pp. 1055–1081, illus. 2; 36, pp. 1083–1107*).—In addition to brief seasonal survey notes from the Emergency Plant Disease Prevention Project relating to such crops as cereals and grasses, corn, sorghums and related plants, field legumes, peanuts, potatoes, sweetpotatoes, celery and other vegetables, fruits, special crops, and miscellaneous plants, the above issues contain the following signed notes and articles:

No. 33.—Some cinchona diseases in the Western Hemisphere, by W. C. Davis and B. S. Crandall; further note on elm dying and phloem necrosis in Indiana, by J. S. Tidd; observations on *Phymatotrichum* root rot of guayule, by J. T. Presley; cotton diseases in New Mexico by W. G. Hoyman and in Oklahoma by H. W. Larsh; tobacco diseases in Maryland, by E. A. Walker; diseases on cowpeas in Arkansas and Oklahoma, by H. W. Larsh; diseases observed on various leguminous hosts in Mississippi and Louisiana, by D. C. Bain; diseases of snap beans and lima beans in North Carolina, by A. E. Prince; diseases of pinto beans in New Mexico during 1943 and 1944, by W. G. Hoyman; bean diseases in western Washington, by L. W. Boyle; potato diseases in Wisconsin, by E. E. Honey, R. E. Vaughan, and J. W. Brann; summary of the vegetable disease situation for 1944 in Massachusetts, by O. C. Boyd; and diseases and injuries of apple in Connecticut, by R. C. Cassell.

No. 34.—Fungi associated with decline of avocado and citrus in California, by J. V. Harvey; varietal susceptibility of currants to the cane blight organism and to currant mosaic virus, by E. M. Hildebrand and P. V. Weber; spray experiments with organic fungicides for the control of apple bitter rot, by J. C. Dunegan, J. W. Roberts, and M. C. Goldsworthy; corn root rot in Iowa in 1944, by E. F. Vestal; diseases of corn in Nebraska and Kansas, by C. M. Slagg; potato diseases in Wisconsin, by E. E. Honey and R. E. Vaughan; and asparagus rust in northeastern Illinois, by J. S. Tidd.

No. 35.—Observations on phloem necrosis of elm in Kentucky, Ohio, Indiana, and Illinois, by T. W. Bretz; can the adverse effects of virus diseases be corrected by extra fertilization and pruning the Montmorency cherry? by E. M. Hildebrand; pecan diseases in Oklahoma, by H. W. Larsh; diseases of storage crops in New England during the winter of 1943–44, and condition and diseases of potatoes in Aroostook County, Me., both by R. C. Cassell; diseases of pimento peppers in Georgia, by G. M. Stone; boron deficiency of rutabagas in southwest Virginia, by E. K. Vaughan and G. M. Shear; oats disease survey in northern Pennsylvania, by J. S. Niederhauser; corn diseases in north central Illinois, by J. S. Tidd and G. H. Boewe; rots of runner peanuts in southeastern Alabama, by G. M. Stone and C. Wilson; and diseases of peanuts in North Carolina, by A. E. Prince.

No. 36.—Potato storage in the Red River Valley of Minnesota, by I. W. Tervet; stem rot and other diseases of sweetpotatoes in the New Jersey-Delaware-Maryland area, by E. A. Walker; sweetpotato stem rot survey in South Carolina, by A. E. Prince; sweetpotato diseases in Indiana and Illinois, by J. S. Tidd; and rice diseases in Arkansas, by H. W. Larsh, and in Texas in 1944, by E. C. Tullis and G. E. Altstatt.

Cornell University abstracts of theses, 1943 (*Ithaca, N. Y.: Cornell Univ. Press, 1944, pp. 323–329, 333–338, 342–344, 347–356, 418–419*).—The following are of interest to plant pathology: A Study of Frost Injury and Resistance in Garden Roses, by G. N. Asai (pp. 323–326); *Fusarium* Wilt of Spinach, by O. S. Cannon (pp. 327–329); Powdery Mildew of Barley—Studies of Yield Losses and the Inheritance of Disease Resistance, by N. F. Jensen (pp. 333–334); Studies on Spray and Dust Schedules for Control of Apple Scab in Western New York, by F. H. Lewis (pp. 335–338); The Rust of Greenhouse-Grown Spearmint and Its Control, by J. S. Niederhauser (pp. 342–344); Some Studies on the Dutch Elm Disease and the Causal Organism, by S. A. Pope (pp. 347–348); Studies of Phytopathogenic Bacteria, by M. P. Starr (pp. 349–350); Effect of Temperature and Relative Humidity on Occurrence of Blossom Blight of Stone Fruits, by L. O. Weaver (pp. 351–353); Suscept Range of the Potato Yellow Dwarf Virus, by S. G. Younkin (pp. 354–356); and The Volatile Production of Apples and Its Possible Relation to the Apple Scald Disease, by F. W. Southwick (pp. 418–419).

[Abstracts of papers] (*Va. Acad. Sci. Proc., 1944, pp. 42, 48, 73*).—The following are included: Studies in the Physiology and Genetics of *Colletotrichum* *phomoides*, the Tomato Anthracnose Organism, by C. W. Roane and E. K. Vaughan, and Black Shank, a Little Known But Serious Threat to Tobacco Production in Virginia, by E. K. Vaughan (both Va. A. and M. Col.); and Technique for Measuring Resistance to Black Root Rot in Tobacco, by R. G. Henderson (Va. Expt. Sta.).

Plant diseases in Texas and their control, A. A. DUNLAP and J. F. ROSBOROUGH. (Coop. Tex. Expt. Sta. and U. S. D. A.). (*Tex. Agr. Col. Ext. [Bul.] 132 [1944], pp. 73, illus. 29*).—A revision of Texas Station Circular 91 (E. S. R., 85, p. 357).

Notes on Wisconsin parasitic fungi, III, H. C. GREENE (*Wis. Acad. Sci., Arts, and Letters, Trans., 35 (1943), pp. 113–135*).—These miscellaneous notes (E. S. R., 89, p. 221; 91, p. 693), including additional plant hosts and additional species, are based chiefly on collections made during 1942.

Supplement to the revised list of plant diseases in Tanganyika Territory, G. B. and M. M. WALLACE (*East African Agr. Jour., 10 (1944), No. 1, pp. 47–49*).—This list includes also a small number of fungi recorded on noneconomic plants.[1]

Some aspects of plant pathology in Western Australia, W. P. CASS SMITH (*Jour. Austral. Inst. Agr. Sci., 10 (1944), No. 3, pp. 93–101*).—An address discussing the history, contributions to agricultural progress, present activities and problems, future trends, and organization of plant pathology in this area.

Electrokinetic studies on Erwinia amylovora and Phytomonas stewartii in relation to virulence, V. L. FRAMPTON and E. M. HILDEBRAND. (*Cornell Univ.*). (*Jour. Bact., 48 (1944), No. 5, pp. 537–545, illus. 1*).—Pathogenicity or virulence in *E. amylovora* was not found correlated with electrophoretic velocity, and in neither species was the virulence of the pathogenic strains correlated therewith. Mobility-pH curves at constant ionic strength were determined for both organisms and appeared to be distinctive for each species. It was noted that age, storage, kind of media, and serum globulin (horse) did not affect the mobility of *E. amylovora.*

Notes on seed-borne fungi.—II, Alternaria, J. W. GROVES and A. J. SKOLKO (*Canad. Jour. Res., 22 (1944), No. 5, Sect. C, pp. 217–234, illus. 25*).—In this contribution (E. S. R., 92, p. 64), seven species of this fungus genus—of which six are definitely pathogenic—are reported to have been isolated from crop plant seeds. Cruciferous plants were attacked by three distinct species: *A. brassicae, A. oleracea*, and *A. raphani* n. sp.—here described; the last was isolated only from radish seeds. Two species were found on carrots: *A. radicina* and *A. dauci* n. comb.; a species close to *A. dauci* was isolated from flax and is described as *A. linicola* n. sp. The name *A. tenuis* is here used to include the generally saprophytic forms that have been isolated from seeds of a wide variety of plants; they exhibit many variations in culture characters, spore markings, etc., but all have spores falling within the range 20µ–50µ × 10µ–16µ. There are 31 references.

Inducing sporulation of Alternaria solani in culture, S. E. A. MCCALLAN and S. Y. CHAN (*Contrib. Boyce Thompson Inst., 13 (1944), No. 7, pp. 323–335, illus. 3*).—Undisturbed cultures of most isolates produced few spores or none, while potato dextrose agar cultures scraped and placed on a window sill sporulated more or less readily; other media tried or addition of various vitamin B components in conjunction with the above scraping and exposure were without effect or no better than the potato dextrose agar. Maximum vegetative growth and sporulation of scraped cultures occurred at 20° C.; at this temperature, sporulation tended to increase with decrease in relative humidity. Even with optima of both temperature and humidity, however, the spore yield of controls exposed on the window sill was not attained. Cultures exposed to irradiation from an open mercury arc lamp sporulated abundantly, under favorable conditions yielding about

---

[1] East African Agr. Jour., 2 (1937), No. 4, pp. 305–310.

10 million spores per petri dish culture. Scraped cultures produced a maximum of spores following about 20 seconds' exposure; unscraped cultures required longer and produced less than one-sixth as many spores. Scraping before or after irradiation made no significant difference in yield. Maximum spore yields were obtained at 10-cm. distance from the lamp and with 2-week-old cultures. Following scraping and irradiation, there was a pronounced optimum at 20° for greatest sporulation. Irradiation through color glass filters markedly affected sporulation, which increased as the wavelength transmitted decreased. Greatest sporulation was obtained with filters whose limits of transmission were 249–254 mμ. Spores produced by irradiated cultures were equal in infective power to those from cultures exposed on the window sill. Maximum sporulation of this fungus (Maine strain 52) may be induced by growing on potato dextrose agar for 2 weeks at 20°, scraping, exposing to ultraviolet light for 20 sec. with lamps or filters transmitting to about 250 mμ, and returning to 20° for 2 days.

Ascochyta meliloti (Trel.) Davis as the conidial stage of Mycosphaerella lethalis Stone, F. R. JONES. (U. S. D. A. coop. Wis. Expt. Sta.). (*Wis. Acad. Sci., Arts, and Letters, Trans., 35 (1943), pp. 137–138*).—An amended description is included.

Penicillin treatment of crown gall, J. G. BROWN and A. M. BOYLE. (Ariz. Expt. Sta.). (*Science, 100 (1944), No. 2606, p. 528*).—In further tests of penicillin against plant pathogenic bacteria (E. S. R., 92, p. 65), crown galls on bryophyllum induced by inoculation with *Agrobacterium* (*Phytomonas*) *tumefaciens* were destroyed by wrapping antiseptic cotton soaked in crude penicillin around them after puncturing the galls in numerous places with a sterile needle. The method is suggested for trial on nursery stock and set trees and other plants with galls limited to crown and other aerial parts.

A comparison of the toxicity of certain dyestuffs to the conidia of Fusarium culmorum, W. M. DION and K. A. LORD (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 221–231*).—As determined by the slide-germination technic, the toxicity of the basic dyes tested against spores of *F. culmorum* and *Cercosporella herpotrichoides* was unaffected by the acid radicle associated with the dye base. The high toxicity of malachite green to *F. culmorum* was reduced weight for weight and mole for mole by substituting ethyl, propyl, or butyl for the methyl groups. Reduction of this dye to malachite green leuco base removed its toxicity. Substitution of amino and alkylated groups in benzene nuclei of triphenyl methane increased the toxicity; acid groups reduced it. Sulfonation and carboxylation reduced toxicity to the vanishing point. Alkylation of amino groups increased the toxicity, but alkylation of benzene nuclei did not appreciably affect it. When the central C atom of the triphenyl methane dyes was replaced by N the diphenyl ammonium compounds were less toxic than the corresponding triphenyl methane compounds. Prevention of rotation of the animated benzene rings by bridging—in the *o*-position to central atom—with O or N, and so obtaining a planar molecule, only slightly affected the toxicity. Certain dyes stimulated fungus growth. The toxicity of the basic dyes seems thus to depend not on one specific part but on the molecule as a whole; within limits the structure may be varied without pronounced toxicity changes.

A new parasitic red alga from southern California, E. Y. DAWSON (*Bul. Torrey Bot. Club, 71 (1944), No. 6, pp. 655–657, illus. 4*).—*Loranthophycus californicus* n. gen. and sp. (Delesseriaceae)—parasitizing sterile fronds of an undescribed alga of the same family—is described.

Brazilian chytrids.——IV, Species of Rozella, J. S. KARLING (*Mycologia, 36 (1944), No. 6, pp. 638–647, illus. 28*).—Six species (one new) of this fungus genus parasitizing the mycelium or sporangia of *Pythium, Achlya, Cladochytrium, Endochytrium, Rhizophlyctis,* or *Rhizophydium* are considered. Five of these six hyperparasites have been recorded previously from the United States; their discovery in South America indicates this genus to be widely distributed geographically as well as in host range.

Untersuchungen über den Einfluss der Hitze auf den Rostparasitismus [Investigations of the influence of heat on rust parasitism], W. STRAIB and A. NOLL (*Zentbl. Bakt.* [*etc.*], *2. Abt., 106* (*1944*), *No. 13–15, pp. 257–277*).—Supplementing earlier studies of the influence of temperature on rust parasitism, the author investigated the action of supramaximum temperatures on the course of infection and behavior of the host plants against *Puccinia glumarum* and *P. triticina,* as well as their histological relationships. In this work heat was applied by immersion of the experimental plants in water heated to the desired temperature. Under like duration of treatment applied several days after inoculation, the external signs of resistance (chlorosis and necrosis) in suitable wheat varieties increased and then decreased in distinctness with rises in temperature up to about 35° C. For attainment of the same resistance picture at the higher temperatures—paralleling the results of warm-air treatment in earlier studies—an essentially shorter action time was needed than for the lower temperatures. To evoke resistance at 25°, immersion for 16 hr. sufficed; at 30°, 2 hr.; and at 50°, 1 sec. For complete suppression of fructification in the two fungi, 30° for about 15 hr., 40° for 10 min., and 50° for 5 sec. were necessary—in each case with treatment of the plants 5 days after inoculation; with earlier application of heat the duration of treatment was correspondingly shortened. Heat treatment of wheat leaves before inoculation led to increased susceptibility to both rust fungi; this was particularly noticeable in the highly resistant varieties of wheat. The most pronounced effects with both pathogens occurred at a water temperature of 50° applied for 40 sec. The effects were indicated macroscopically by break-down of the leaf spots and promotion of fructification in the parasites. The decreases in resistance thus induced were specific for both races and varieties of wheat, but the original degree of resistance of the host plant was later regained. Under the influence of high temperatures applied after infection had taken place, a gumlike substance was formed in the mycelium of both fungi, such as occurs in absolute host resistance. Values were ascertained for the minimum heat-application time needed for the formation of this substance, as well as for its rate of production. Heating the leaf blades before infection led to a temporary inhibition of the production of this gumlike substance and promotion of mycelial growth. An attendant phenomenon of resistance to these fungi was the more or less pronounced silicification of the tissues. The temperature-determined resistance depends on the greater heat susceptibility of the fungus itself; both species—as well in young as in old stages of infection—exhibited similar behavior to the applied heat, the hyphae becoming inhibited in growth and the haustoria frequently deformed and silicified. The different heat-determined types of infection were also recognizable microscopically by mycelial forms described in the text. Comparison of the microscopical behavior of *P. glumarum tritici* and the host cells in the so-called summer or field resistance of wheat varieties indicated a close correlation with the behavior of seedlings elicited by heat shock.

Untersuchungen über Wundreaktionen des Weizenblattes und ihre Beziehungen zur Rostinfektion [Studies of the wound reactions of wheat leaves and their relations to rust infection], A. NOLL (*Zentbl. Bakt.* [*etc.*], *2. Abt., 106* (*1944*), *No. 13–15, pp. 277–285*).—Formation of the gumlike substance in wounded wheat leaves was found strongly favored by high environal moisture. The optimum temperature for its production in wounds immersed in water was about 36° C., the process under these conditions being completed in about 10–12 hr. Formation of this material is said to be a resistance reaction of the wheat plant against attack by bacteria on the wound. After heat treatment of the leaves for about 20 sec. at 50° before wounding, this cell product was no longer produced and the wound became a focal point for tissue decay. After the action of frost, chloroform, and other factors described in the text the production of this material was prevented; the same was true in leaf infection by *Puccinia glumarum*. Etiolation of the plants led to no such inhibition. After a certain time following application of heat the tissues regained their original resistance and the ability to form this cell product; they were also protected against a repeated heat shock. The leaf cells around the wound became encrusted with large amounts of silicic acid. In etiolated leaves, the chloroplasts in the cells bordering the wound surface retained their normal form and color longer than in other parts; the nuclei of such cells were also more deeply stained with Delafield's haematoxylin than the other nuclei. Close resemblances were observed between these wound reactions and the resistance reactions of the host cells to rust infection—particularly as to the relations of temperature.

A new genus of smuts, M. J. THIRUMALACHAR (*Mycologia, 36 (1944), No. 6, pp. 591–597, illus. 11*).—This smut fungus, found on a tree—*Heptapleurum venulosum*—common in the mixed forests of Mysore, is described as *Mundkurella heptapleuri* n. gen. and sp. (Ustilaginales).

Two new records of Sphaceloma diseases in the United States, A. E. JENKINS. (U. S. D. A.). (*Phytopathology, 34 (1944), No. 11, pp. 981–983, illus. 1*).—The author reports scab (*S. araliae*) on *Aralia spinosa* in a nursery in northeastern Missouri and gray scab (*S. murrayae*) on *Salix lasiandra* in Washington State.

The germination of the seed of Striga lutea.—I, Host influence and the progress of germination, R. BROWN and M. EDWARDS (*Ann. Bot. [London], n. ser., 8 (1944), No. 30–31, pp. 131–148, illus. 8*).—This parasitic flowering plant attacks the roots of various hosts of which corn, sorghum, and sugarcane are the most economically important. The majority of its seeds germinate only when exposed to stimulating material from the host roots; two methods are described for studying the quantitative aspects of the host-parasite relation in germination. The germination rate after exposure to the host stimulus was found to be enhanced by previous exposure of the seeds to moist warm conditions—believed to indicate that the host factor operates only at a comparatively late stage in germination. Although the majority of the seeds failed to produce a radicle unless exposed to the host factor, a small proportion under suitable treatment did so without it. In composite cultures of host roots and seeds of the parasite the frequency of germinated seeds tended to fall with increasing distance from the host root; this is believed to be the effect of a corresponding gradient in the concentration of the material from the host root. Comparison of the germination frequency along individual roots showed that those from different seedlings varied considerably in the rate of secretion of the host factor; observations of germination frequency at intervals in successive zones of a vertical series across which a host root grew indicated the secretion of the stimulant to occur only at the root tip. Germination along a host root was enhanced by production of laterals—attributed to the consequent development of additional root tips. It is suggested that since—with *S. lutea* seeds and possibly also with those of other similar parasites—germination can be arrested at a comparatively late stage by withholding the host factor without at the same time disturbing normal metabolic processes, such seeds may provide favorable material for studies of germination.

Direct and indirect actions of radiation on viruses and enzymes, D. LEA, K. M. SMITH, B. HOLMES, and R. MARKHAM (*Parasitology, 36 (1944), No. 1–2, pp. 110–118, illus. 4*).—When tobacco mosaic virus at various concentrations was inactivated by γ-rays, the inactivation dose was independent of concentration at the higher concentrations, and at low concentrations it also attained a constant but lower value. Over an intermediate range the inactivation dose increased with concentration of virus. These results are explained on the basis that when the virus is irradiated dry or in concentrated solution the inactivation is direct and due to ionization produced inside the virus particle; at lower concentrations the inactivation is largely indirect and due to ionization of the water. Gelatin added to the solution protected the virus against the indirect action of radiation. Curves are given of the inactivation of dry preparations of ribonuclease and adenylpyrophosphatase (myosin) by X-rays. On the assumption that a single ionization in an enzyme molecule leads to its inactivation, it is shown that measurement of the inactivation dose leads to a rough estimate of the molecular weight of the enzyme. There appears to be no fundamental difference between viruses and enzymes in their mechanism of radiation inactivation.

Descriptions and revisions of several species of viruses in the genera Marmor, Fractilinea, and Galla, H. H. McKinney. (U. S. D. A.). (*Jour. Wash. Acad. Sci., 34 (1944), No. 10, pp. 322–329*).—Several species and varieties of viruses infecting cereal and forage grasses are here described and named, and the descriptions of the wheat mosaic-rosette and tobacco ring-spot viruses are emended—the latter being transferred to the genus *Marmor* Holmes emend. The virus of mild dark-green mosaic in tobacco is described and named. The viruses of cereal grasses in Russia and Siberia are placed in the genus *Fractilinea*. The wheat mosaic viruses reported from Japan are believed very similar to the soil-inhabiting wheat mosaic viruses east of the Mississippi River, and no attempt is at present made to separate them. The virus of wallaby ear of corn is placed in the genus *Galla*. There are 37 references.

Some viruses transmitted by agallian leafhoppers, L. M. Black (*Amer. Phil. Soc. Proc., 88 (1944), No. 2, pp. 132–144, illus. 7*).—As a result of this study, a new genus, *Aureogenus*, is proposed to include potato yellow dwarf virus and two new potato viruses here described. It is further proposed that the New York potato yellow dwarf virus be named *A. vastans* var. *vulgare* n. comb; the New Jersey yellow dwarf virus, *A. vastans* var. *agalliae* n. comb.; and the new viruses, *A. magnivena* and *A. clavifolium* n. spp., respectively. The transmission tests were done on crimson clover. The New York virus was transmitted by *Aceratagallia sanguinolenta* (Prov.), *A. lyrata* (Baker), *A. obscura* Oman, and *A. curvata* Oman, but not by *Agallia constricta* Van Duz.; it was transmitted by only 2 of 465 *A. quadripunctata* (Prov.) and possibly by 1 of 220 *Agalliopsis novella* (Say). The New Jersey virus was transmitted by *Agallia constricta* and *A. quadripunctata* but not by *Aceratagallia sanguinolenta;* it is also possible that 1 of 241 *Agalliopsis novella* transmitted this virus. *Aureogenus magnivena* was transmitted by *Agallia constricta, A. quadripunctata,* and *Agalliopsis novella* but not by *Aceratagallia sanguinolenta. Aureogenus clavifolium* was transmitted by *Agalliopsis novella* but not by *Aceratagallia sanguinolenta, Agallia constricta,* or *A. quadripunctata.* There was evidence that the cases of rare transmission were real and not due to contamination.

Rootrots of cereals and grasses in North Dakota, R. Sprague. (Coop. U. S. D. A.). (*North Dakota Sta. Bul. 332 (1944), pp. 35, illus. 8*).—The increased importance of grass crops in the northern Great Plains stressed the need for this restudy of the causes of poor stands and low yields in grains and grasses due to soil fungi. The symptoms of root rot in North Dakota cereals and grasses were found separable into four types of injury: (1) Preemergence seed and seedling rots due to *Pythium debaryanum, Helminthosporium sativum, Fusarium* spp., and various molds, particularly in early spring, with *P. arrhenomanes* causing seed rot in later seedings; (2) damping-off due to *P. debaryanum* and related species soon after seedling emergence; (3) root browning or seedling blight due to *P. arrhenomanes* and causing cool-season grasses to wither and die about 6 weeks after April seeding and warm-season grasses, corn, and sorghum to be affected when seeded early before the soil is thoroughly warm; and (4) general root decay or necrosis due to *H. sativum, Fusarium* spp., *Curvularia geniculata,* and to some extent to *Pythium* spp. This injury is not confined to any period in the plant's growth, although most of the injury occurs in summer.

The most important fungus root parasites of grasses and wheat in the State are *P. arrhenomanes* and *H. sativum,* respectively; they attack almost all cereals and grasses. There are a number of strains of the root necrosis and damping-off Pythiums varying in ability to attack certain grass and nongrass hosts. Oats are moderately susceptible and wheats resistant to most of them; small seeded grasses such as blue grama and such grains as proso are usually highly susceptible when seeded in cool moist soil. Most Fusariums found in North Dakota are important only as early-season seed rots, but the much more parasitic scab-producing species are present in the Fargo area. *Rhizoctonia solani* is common on cereal and grass roots during wet weather, but most strains are not highly parasitic to most grasses and cereals in the State; it sometimes causes eye-spot at the stem bases of wheat. Pink root in maturing cereals and grasses is mainly due to a nonparasitic development of *F. oxysporium* or to a nonparasitic or semiparasitic attack by *Phoma terrestris.* The latter sometimes rots seeds of sorghums and corn during wet retarded early-season weather. Several common molds (e. g., *Alternaria* spp.) are nonparasitic on living cereals and grasses, but *C. geniculata* sometimes has strains causing root decay in some cereals and grasses.

Physiologic specialization of Puccinia glumarum Erikss. and Henn. in China, C. T. Fang (*Phytopathology, 34 (1944), No. 12, pp. 1020–1024*).—Nine physiologic races (C1–C9) of *P. glumarum* in 43 collections—most of them from Yunnan Province, China—were separated on differences in infection type on 7 varieties of wheat and 1 variety of barley. Of 1,487 varieties tested for reaction to these races, 30 proved either immune or highly resistant; since only 2 of the 30 were of Chinese origin, introduction of breeding material into that country may be advisable.

Pathogenicity on Avena and growth response of Pseudomonas coronafaciens (Elliott) Stapp, C. H. Kingsolver (*Iowa State Col. Jour. Sci., 19 (1944), No. 1, pp. 29–31*).—Abstract of thesis.

Soil conditions and the take-all disease of wheat.—VIII, Further experiments on the survival of Ophiobolus graminis in infected wheat stubble, S. D. Garrett (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 186–191*).—In this installment (E. S. R., 87, p. 382), assimilable nitrogen in various forms is shown to prolong the life of *O. graminis* in infected wheat straw, whether added directly to it or to the surrounding soil. When the infected straws were buried in washed quartz sand, 0.5 gm. N per 100 gm. air-dry straw proved the optimum dressing for longevity of the fungus; adding sodium phosphate did not significantly increase it. N is considered to prolong the life of *Ophiobolus* by enabling the mycelium to form new branch hyphae, which can explore unexhausted parts of the substrate; it is suggested that aged mycelium dies from carbohydrate starvation, through exhaustion of the zones of enzymic erosion around the hyphae. This hypothesis is supported by the extended life of the fungus in infected straws shaken twice weekly in 3 percent dextrose solution. *Ophiobolus* was found to survive longer in infected straws buried in a fallow soil than in the same soil under oats, mustard, or trefoil; this suggests the use of catch crops as competitors with the fungus for soil N.

Studies on seed treatments for cereal crops, W. E. Brentzel (*North Dakota Sta. Bul. 331 (1944), pp. 19, illus. 2*).—Ten proposed requirements of a satisfactory disinfectant are listed, and the results of seed treatment tests are presented. The plant emergence and seedling vigor from low test weight wheat were increased and oats smuts were satisfactorily controlled by seed treatment with an organic mercurial. The emergence from barley with low germination was considerably improved by either of two organic mercurials, and covered smut and stripe were controlled, emergence from blighted (*Helminthosporium* spp.) seed was increased, and smut of proso was prevented by ethyl mercury phosphate seed treatment. The stand of emmer was improved and smut reduced by organic mercurials. No apparent injury occurred in hard spring wheat stored 172 days after treatment with ethyl mercury phosphate or in durum wheat stored 285 days after treatment with the latter or with copper carbonate or basic copper sulfate. Four oats varieties treated with ethyl mercury phosphate were stored 48 days, also without injury. The emergence of hard spring wheat in soil generally was 7–14 percent lower than the official blotter germination and that of amber durum 1–8 percent lower; the figures for seed treated with ethyl mercury phosphate were 2.3 below and 2.4 percent above, respectively. It thus appears that only when treated with a suitable organic mercurial will wheat give an emergence approximately equal to the official germination. The emergence of flax in soil was 10–32 percent below that in the official blotter test. The average decrease from seven lots of seed was 18 percent; treatment with ethyl mercury phosphate reduced this difference to 10 percent.

Seed treatments, W. E. BRENTZEL (*North Dakota Sta. Cir. 69* (*1944*), *pp. 16, illus. 10*).—A revision of Circular 56 (E. S. R., 73, p. 194).

The short wet method of seed disinfection, A. E. MUSKETT (*Ann. Appl. Biol., 31* (*1944*), *No. 3, pp. 218–221, illus. 5*).—As good results against helminthosporium disease of oats were obtained by this as by the dusting method, Ceresan being employed. Suitable apparatus is necessary for the method, and two of the machines manufactured for the purpose are described.

Parasitism of Rhizoctonia solani on beans, L. H. PERSON. (La. Expt. Sta.). (*Phytopathology, 34* (*1944*), *No. 12, pp. 1056–1068, illus. 4*).—*R. solani* can induce damping-off and stem rot in beans under a rather wide range of temperature and soil moisture. The 27 isolates studied comprised a number of strains differing in culture characters and growth rate at different temperatures. Four rather clear-cut groups of isolates were distinguished on the basis of pathogenicity to beans: (1) Isolates from sugarcane and from sclerotia on potato tubers were nonpathogenic to beans; (2) those from peas caused a very slight amount of damping-off and a moderate stem infection; (3) the isolate from rice almost completely prevented emergence but caused less severe stem lesions than the pea isolates; and (4) isolates from bean, tomato, eggplant, and sugar beet proved capable of reducing stands somewhat and caused very severe stem lesions. The isolates in groups (2) and (4) could be further subdivided when cowpeas, English peas, soybeans, and broadbeans were added as differential hosts. The nonpathogenicity of the sugarcane and potato isolates is of interest and may be of possible importance when considering a rotation system for the alluvial sections of Louisiana. The above hosts are important economic crops in some of these areas.

Thermal inactivation of southern bean mosaic virus, W. C. PRICE (*Amer. Jour. Bot., 31* (*1944*), *No. 8, pp. 4s–5s*).—An abstract.

The reaction of varieties of Trifolium subterraneum to attack by Uromyces trifolii as a heritable character, K. L. HILLS (*Jour. Council Sci. and Indus. Res.* [*Austral.*], *17* (*1944*), *No. 2, pp. 74–78*).—The variety (Mt. Barker) of subterranean clover commonly grown in Australia is very susceptible to leaf rust; other varieties—particularly the early maturing types—are not attacked. By crossing Mt. Barker with the early Mulwala, it was shown that resistance to this disease is an inherited character, although early maturity tends to be associated with resistance. Both early and late segregates, however, have been obtained in the third generation of the cross which are immune and possess to a large extent the agronomic characters of the parents.

Factors influencing the development of cotton diseases, L. Ling (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 194–204, illus. 6*).—Under local conditions in Szechuan Province, West China, the incidence of most cotton diseases was observed to be influenced chiefly by air humidity. For sore shin, however, soil moisture and soil temperature have a more profound influence. In the case of cyrtosis—caused by leafhopper injury—the disease appears earlier with higher temperatures during the period of rapid reproduction of the insect, whereas heavy rainfalls reduce the intensity. Environal modification by varying the time of sowing influences the incidence of diseases affecting both seedlings and mature stages. Among seedlings the prevalence of anthracnose is influenced chiefly by air humidity; sore shin, on the other hand, requires a moist soil for spread and development. In the mature plant, late sowings increase the intensity of cyrtosis but reduce bacterial blight and anthracnose. As to culture practices, nitrogenous fertilizers generally increased the incidence of most diseases; denser stands and closer spacing brought a heavier infection in stem and leaf diseases but not in boll diseases; and a mixed cropping system apparently had no effect on the fungus and bacterial diseases but reduced the intensity of cyrtosis when the crop interplanted was not susceptible to leafhopper infestation.

Phoma stem disease of flax, C. R. Millikan (*Jour. Austral. Inst. Agr. Sci., 10 (1944), No. 3, pp. 129–130, illus. 1*).—A note on stem spotting in Victoria by *Phoma* sp., with symptoms apparently not those usually reported for flax infection with *Phoma* spp.

Physiologic specialization and the control of millet smut, C. S. Wang. (Minn. Expt. Sta.). (*Phytopathology, 34 (1944), No. 12, pp. 1050–1055*).—Of 9 collections of *Ustilago crameri* from China tested for pathogenicity on 12 millet varieties, 6 differed sufficiently in virulence on 5 differential hosts to be considered physiologic races. Although there were great differences in varietal reaction to smut races, no variety was resistant to all. Of 11 fungicides tested as seed disinfectants, all except powdered sulfur and formaldehyde dust reduced the smut infection. New Improved Ceresan was very effective, and formaldehyde dip, Cuprocide, copper carbonate, and Barbak III were fairly so; sulfur fungicides in general were not satisfactory.

Macrophomina root and stem rot and anthracnose of Chamaecrista, J. L. Weimer. (Ga. Expt. Sta. coop. U. S. D. A.). (*Phytopathology, 34 (1944), No. 12, pp. 1077–1085, illus. 3*).—Two diseases of *Chamaecrista* (partridge-pea) are described, a root and stem rot and an anthracnose caused by *Macrophomina phaseoli* and *Glomerella cingulata,* respectively. So far as known, the former fungus attacks *C. procumbens* only; the latter is destructive both to this species and to *C. fasciculata.* Under the test conditions, *Macrophomina* was more pathogenic on young plants, but observations indicate that older plants can be killed by it. Anthracnose can kill seedlings in a few days, but only the actively growing ends of the branches of older plants are susceptible and mature plants are highly resistant.

Outline of procedure for the diagnosis of bacterial ring rot of potatoes—report of the committee of the Potato Association of America, D. P. Glick et al. (*Amer. Potato Jour., 21 (1944), No. 11, pp. 311–314*).—The report includes a recommended procedure applicable to routine inspection in field, car, or storage, involving field inspection for vine and tuber symptoms, car or storage inspection for tuber symptoms—including the ultraviolet light test, and elimination of infected tubers; and a procedure to be followed in other than routine inspection (e. g., when routine tests prove unsatisfactory or when recourse to law may be taken in case of the sale of supposedly infected seed tubers), involving the gram stain, isolation and identification of the bacterial agent, transmission of infection to a suitable host, and the ooze test.

Efficacy of the rotary knife in the control of potato ring rot, L. C. KNORR. (Cornell Univ.). (*Amer. Potato Jour., 21 (1944), No. 9, pp. 250–261*).—In two factorial tests of the rotary cutting knife, two $HgCl_2$ cut seed dips, and ultraviolet light against ring spot spread, the first method—with boiling water disinfection of knife—produced higher yields of both healthy and total tubers than the others and also led to a statistically significant reduction in the amount of ring rot-diseased tubers. In both tests $HgCl_2$ seed piece dips gave the greatest control of ring rot spread, but at the same time led to the smallest crop of healthy and of total tubers. Either the extent of the field lay-out or the differences obtained (or both) were too small to show results of statistical significance in controlling ring rot by ultraviolet light. Analyses of covariance showed a high correlation between stand and yield, indicating that the yield of total tubers (healthy + diseased) depended on the effect of the particular treatment on emergence. The picker planter in the field led to an apparent spread of ring rot, but since the difference was not statistically significant, the increase under the test conditions may have been due to variations.

The effect of sulphur and acid fertilizer on incidence of potato scab, J. H. MUNCIE, H. C. MOORE, J. TYSON, and E. J. WHEELER. (Mich. Expt. Sta.). (*Amer. Potato Jour., 21 (1944), No. 11, pp. 293–304*).—Applications of acid fertilizer alone and plus S in bands, plowed under, or disked into the soil reduced infection with *Actinomyces scabies*. The greatest reduction in scab resulted from applying 3,200 lb. S per acre plus acid fertilizer, but the yield was seriously impaired; the least scab occurred in plots with soil reactions of about pH 3.5–3.8. The potato scab organism was only partially inhibited in soils of low pH, and it gradually adapted itself to these conditions. The disease became more severe following addition of lime to bring the soil reaction to about pH 5.6. As compared with the crop of 1939, there was a noticeable decrease in percentage of clean tubers in the two crops following the second application of S in 1940, and this in spite of the fact that the soil pH in most (except the limed) plots remained lower.

Potato scab and seed piece decay control by seed treatment, J. A. BEARE (*Jour. Dept. Agr. So. Austral., 48 (1944), No. 1, pp. 12–13, illus. 1*).—The author reports effective control of scab and seed-piece decay by a new proprietary organic mercurial compound and by zinc oxide. The commercially significant scab in plots grown from untreated seed was about 10 percent, representing a loss of 1 ton per acre.

Transmission of potato virus diseases.—IV, Ground work studies on the growth of normal potato foliage, J. G. BALD (*Jour. Council Sci. and Indus. Res. [Austral.], 17 (1944), No. 2, pp. 94–111, illus. 3*).—A continuation (E. S. R., 90, p. 777). When periodic measurements of leaf area were made on plants of different varieties and strains during the earlier developmental stages, the growth rate of the total area was similar until about the inception of flowering; thereafter, the rates for early strains and varieties were less than for the later ones. The early agreement in leaf growth rate indicated that the metabolic processes underlying growth at that stage were equally efficient for all strains and varieties tested. The number of leaves developing on the main axes were similar. The differences in leaf area among the strains and varieties seemed to arise from differences in the time of inception of several development stages. In the Up-to-Date variety, which has very large leaves on the main axis, the development of axillary shoots occurred later than in varieties with smaller leaves; continued expansion of the leaves on the main axis apparently delayed the formation of axillary shoots. The difference in the times at which axillary growth began was not evident between early and late strains of the same variety. The main determinant of maturity was the growth of axillary shoots. Independently of varietal differences in time of inception of axillary growth, early maturing varieties and strains had a relatively slow axillary growth rate and late maturing ones had a relatively rapid axillary growth rate. It is suggested that differences in maturity are due mainly to competition for growth-promoting substances between above-ground axillary shoots and those below ground on which the tubers form.

Potato wart in America, R. E. HARTMAN and R. V. AKELEY. (U. S. D. A. et al.). (*Amer. Potato Jour., 21 (1944), No. 10, pp. 283–288*).—Potato wart (*Synchytrium endobioticum*) was found still confined to restricted areas in Pennsylvania. Its spread has been controlled by temperature and moisture relationships, immune varieties, and strict quarantine regulations as well as by those governing potato growing in the infested areas. Recently the problem has become more critical, because at least three new biotypes of the organism have been isolated in Europe and a number of varieties formerly believed immune are susceptible to these races; thus far no new races have been found in the United States. Tests of 14 new American varieties and the Dutch variety President indicate that Kathahdin, Mohawk, Sequoia, Mesaba, and Norkota may be considered immune and Houma very resistant. Of 117 seedlings from 14 crosses and 2 selfed lines tested, segregation for resistance occurred in 10; of these, 7 had Kathahdin as a parent. Two selfed lines of Katahdin showed about 50 percent of their seedlings to be very resistant. Of 60 other seedling varieties and commercial sorts tested, 11 proved immune, 4 very resistant, and 45 susceptible.

An Alternaria disease of safflower, S. CHOWDHURY (*Jour. Indian Bot. Soc., 23 (1944), No. 2, pp. 59–65, illus. 2*).—On a leaf spot of *Carthamus tinctorius* observed at Pusa and vicinity and found due to *A. carthami* n. sp., which is described.

Standard and new fungicides for the control of covered kernel smut of sorghum and their effect on stand, E. D. HANSING and L. E. MELCHERS. (Kans. Expt. Sta.). (*Phytopathology, 34 (1944), No. 12, pp. 1034–1036*).—Spergon, Arasan, New Improved Ceresan, DuBay 1452–C, and Corona Coppercarb proved efficient for increasing the sorghum stand and controlling *Sphacelotheca sorghi*. Neither micronized free-flowing sulfur nor micronized wettable sulfur appeared to affect the stand, but both gave satisfactory control of the smut.

The host-parasite relationship in susceptible cantaloups, resistant cantaloups, and cucumbers inoculated with Fusarium bulbigenum (Cke. and Mass.) var. niveum Wr. f. 2, C. E. COX (*Md. Univ. Off. Pub., 41 (1944), No. 6, pp. 14–15*).—An abstract.

A new virus disease of carrots, L. L. STUBBS and B. J. GRIEVE (*Jour. Dept. Agr. Victoria, 42 (1944), No. 9, pp. 411–412, 415, illus. 6*).—According to this preliminary report, a new virus disease of carrots has been responsible over a number of years for partial and in some cases complete failure of this crop in Victoria, Australia; though differing in important points, it somewhat resembles both aster yellows and western celery mosaic in symptoms produced. It was transmitted readily by a common and widespread aphid provisionally identified as *Cavariella aegopodii*. Certain carrot varieties were found tolerant to the disease, and further investigation of this phase of the problem is in progress.

The reaction of green pea varieties to downy mildew and two viruses, N. H. WHITE and T. D. RAPHAEL (*Tasmanian Jour. Agr., 15 (1944), No. 3, pp. 92–93, 97, 104, illus. 1*).—A test of 33 varieties of garden peas against *Peronospora pisi*, Pisum virus 2, and a virus resembling enation virus.

A leaf curl disease of tomato and its relation to some other plants, J. W. L. PEIRIS (*Trop. Agr. [Ceylon], 100 (1944), No. 1, pp. 14–19, illus. 7*).—The disease reported on was characterized by the upward curling, bronzing, and glossiness of leaflets and associated with and experimentally produced by mites. Sulfur dusting or use of a sulfur spray controlled the abnormality. Another type of disease caused by a virus (unpublished data) is distinguished by the upward curling and interveinal yellowing of the leaflets.

Factors influencing infection of the tomato by Verticillium albo-atrum, II, F. M. ROBERTS (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 191–193*).—In further work (E. S. R., 91, p. 45), tomato plants receiving adequate supplies of mineral nutrient were shown to acquire great resistance to infection by this fungus when the leaf-shoot ratio was reduced; this effect is attributed to a reduction in carbohydrate content of the host. Wide variation in potash manuring failed to affect the susceptibility to this pathogen.

Mycosphaerella tulasnei in apple and pear orchards, J. R. KIENHOLZ. (U. S. D. A.). (*Mycologia, 36 (1944), No. 6, pp. 648–649*).—Though *M. tulasnei* has been connected with its imperfect stage *Cladosporium herbarum*, the occurrence of its perithecia on fallen apple and pear leaves appears not to have been reported previously. Notes and measurements based on fresh material are included.

A study of the apple rot fungus Phialophora malorum, L. P. MCCOLLOCH. (U. S. D. A.) (*Mycologia, 36 (1944), No. 6, pp. 576–590, illus. 4*).—The serious losses caused by the fungus warranted further studies (E. S. R., 88, p. 491) on its morphology, physiology, and taxonomy, the detailed results of which are here presented, including an amended description of this variable species. *P. malorum* is primarily a saprophyte living in the surface soil and on the bark and in cankerous woody tissues of apple trees. The fruits become infected on the trees, and under favorable conditions the fungus develops and causes serious and unpredictable losses during storage. The majority of lesions on Winesaps appear to develop around the lenticels, though it is difficult to determine in many cases whether the point of entrance was via the lenticel or through a crack. The fungus also enters through insect and other injuries.

Effect of spray injury on pre-harvest drop of McIntosh apples, F. H. LEWIS. (Cornell Univ.). (*Phytopathology, 34 (1944), No. 12, pp. 1015–1019*).—Under uniform conditions of culture the amount of visible leaf injury and preharvest drop on McIntosh apple trees varied significantly with the spray treatment. Covariance analysis also showed a high correlation between leaf injury and preharvest drop, and both were greatest on trees sprayed with lime-sulfur, lead arsenate, and lime in the cover sprays. Flotation sulfur, lead arsenate, and lime in these sprays caused less leaf injury in July-August and less preharvest fruit drop than lime-sulfur, lead arsenate, and lime. It is believed that the excessive dropping of uninjured fruits from these trees can be explained on the bases of the amount of visible leaf injury, the time of injury, and the effect of the sprays on leaf efficiency.

Strains of prune dwarf, R. S. WILLISON (*Phytopathology, 34 (1944), No. 12, pp. 1037–1049, illus. 3*).—Four strains of prune dwarf virus (Prunus virus 6 or *Nanus pruni*), differing in virulence, were found occurring naturally—two on plum varieties and two on sweet cherry. The relationship of these strains was demonstrated by a comparative study of the symptoms of each in transmission tests with a series of hosts including varieties of *Prunus domestica, P. avium, P. armeniaca, P. cerasifera* (Myrobalan), *P. cerasus, P. mahaleb, P. persica, and P. salicina.* All strains induced strap-shaped rugose thickened leaves and dwarf growth on Italian prune and Lombard plum, stunting and leaf patterns on peach varieties, and leaf markings of various kinds and intensities on cherries and *P. mahaleb.* Symptom expression was either wanting or limited to faint leaf markings and occasionally dwarfing on most of the plum varieties tested. A tendency to recover was noted in peach and cherry varieties after appearance of the initial shock symptoms.

Plagas y enfermedades del cocotero de mayor importancia en la costa del Edo. de Yucatan [Pests and diseases of the cacao tree of major importance in the coastal region of the State of Yucatan, Mexico], L. H. ROBLES G. (*Fitófilo, 3 (1944), No. 2, pp. 3–25, illus. 5*).

Psorosis and related virus disorders on citrus, H. S. FAWCETT (*Calif. Citrog., 30 (1944), No. 1, pp. 14–15*).—A note on this group of disorders and their prevention and treatment.

Principales enfermedades del naranjo en la región de Santa Engracia, Tams. [Principal diseases of the orange tree in the region of Santa Engracia, Tams., Mexico], L. T. CORONA (*Fitófilo, 3 (1944), No. 2, pp. 26–46, illus. 7*).

Granulation and juice quality in Valencias as affected by insecticides, E. T. BARTHOLOMEW and W. B. SINCLAIR. (Calif. Citrus Expt. Sta.). (*Citrus Leaves, 24 (1944), No. 11, pp. 10–11, 17; also in Calif. Citrog., 30 (1944), No. 1, pp. 4–5*).—Supplementing studies previously reported (E. S. R., 85, p. 369), two orange groves became available in which studies could be made of the possible relation of oil spray to granulation in the fruits. The results in one of these groves (1939–44), which had never been sprayed with oil before this experiment began, indicated a definite response to the oil in that granulation was increased and the soluble constituents in the juice were decreased. The response in the second grove were not so clear-cut, but it is pointed out that the long-continued use of oil spray before the present work began may have made it difficult to overcome any hold-over effect of the oil spray; that oil sprays may have a hold-over or residual effect was indicated also in the first grove. As a rule, the larger the fruits the more likely they are to become granulated, but oil spray appeared to augment the amount and severity of granulation regardless of fruit size.

Wilting of shoots in scented geranium (Pelargonium odoratissimum), M. J. THIRUMALACHAR (*Nature [London], 154 (1944), No. 3912, pp. 515–516, illus. 2*).—Ascribed to attack by *Sphaeropsis* sp., possibly *S. pelargonii*.

Diseases of the gladiolus, I, II (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 204–210, illus. 1; pp. 211–218, illus. 8*).

I. *Control of hard rot, due to Septoria gladioli Passer., by fungicidal treatment of the corms,* L. E. Hawker.—Losses from hard rot were reduced by treating the dehusked corms before planting with Hg_2Cl_2, $HgCl_2$, the proprietary mercurials—Aretan, Uspulun, and Ceresan—and by one nonmercurial—Folosan, the first proving least effective. All treatments were less satisfactory on corms with definite lesions. The weight of clean corms produced per old corm planted was usually increased by all treatments—calomel and Ceresan being least effective in this respect. $HgCl_2$ (3 hr. steep in 0.1 percent) was not rendered more effective by adding HCl or by a preliminary dip in methylated spirits to facilitate wetting, while a proprietary wetting agent—Agral—was definitely harmful to the corms and usually less effective than the $HgCl_2$ alone. November had some advantages over March as the time for treatment. All the mercurials tended to delay flowering, this being most marked in the presence of a wetting agent. Stunted foliage and poor quality flowers resulted from use of Ceresan.

II. *Experiments on dry rot disease caused by Sclerotinia gladioli Drayt.,* L. E. Hawker, R. J. Bray, and T. W. Burrows.—As shown by inoculations, young corms are the more susceptible but become less so as they develop, infection occurs in unwounded corms, and inoculation at the top of an old corm is more effective than at the side or base. The percentage of new corms produced from infected corms varied from 0 to 100, according to soil conditions. The disease is favored by wet soil. Removal of leaf bases increased the susceptibiilty of corms planted in contaminated soil, but the presence of these husks was not effective in control; dehusking did not increase the number of diseased young corms in an infected stock planted in new soil. No striking varietal differences in resistance were found. When corms of a diseased stock were treated with Hg_2Cl_2, $HgCl_2$, or Aretan, good control was obtained, calomel giving the most consistent results. Red copper oxide, formalin, and Ceresan were harmful. Sterilization of contaminated soil with formalin, $HgCl_2$, Aretan, or Uspulun gave good but not complete control, the first being least effective.

"Oedema," or "wart," of cultivated violet identified as scab, A. E. JENKINS. (U. S. D. A.). (*Jour. Wash. Acad. Sci., 34 (1944), No. 11, pp. 352–357, illus. 1*).—The author reports the recent identification of oedema or wart of *Viola odorata* as the disease now known as scab and caused by *Sphaceloma violae*. A summary of its known distribution indicates that it has been found in the United States in all coastal areas from Massachusetts to Texas (except Delaware); outside this country its known geographic range includes New South Wales and the Union of South Africa. There are 16 references.

Chlorine gas injures trees, L. H. JONES and M. A. MCKENZIE. (Mass. Expt. Sta.). (*Arborist's News, 9 (1944), No. 12, pp. 89–90*).—A note on Cl gas injuries, with report on a case and on laboratory tests suggesting that chlorinated water can be dangerous to plants only as the gas is released from solution and passes through the stomata of the leaf, where it destroys the chlorophyll.

American and blight-resistant chestnuts, R. B. CLAPPER and R. K. BEATTIE. (U. S. D. A.). (*Flower Grower, 31 (1944), No. 10, pp. 488–489, 500, illus. 4*).—A brief presentation of the history of the chestnut blight in America, of breeding for resistance to it, and of the status of American and oriental Castaneas in the United States today.

Distance as a dosage factor in the spread of Dutch elm disease, G. A. ZENTMYER, P. P. WALLACE, and J. G. HORSFALL. (Conn. [New Haven] Expt. Sta.). (*Phytopathology, 34 (1944), No. 12, pp. 1025–1033, illus. 2*).—When plots were established around large spontaneously infected elms located at least a half mile from other sources of *Ceratostomella ulmi,* the probability that a tree would become infected was found to decrease directly with the logarithm of the distance from the source of infection; spread of the fungus thus follows the logarithmic dose-response relation found in many biological investigations. Since a rectilinear relation exists between the logarithm of the distance and the percentage of infection (as probits), distance from a source of inoculum has an effect inversely equivalent to that of dosage of spores. A regression line calculated from the data proved useful in determining probabilities of infection for trees at varying distances from the disease source and thus is of value in local control measures. Probabilities of infection at 500 ft. under the conditions of these plots were approximately 1 in 500. New infections were markedly restricted to the immediate vicinity of the original infected trees, 75 percent of the newly diseased trees being within 100 ft. and 40 percent within 75 ft. of the original source of infection. Statistically, the difference in amount of infection between the north and south halves of the combined plots was at the margin of significance. Prevailing south winds during beetle emergence probably caused this divergence.

Sapstreak, a new killing disease of sugar maple, G. H. HEPTING. (U. S. D. A.). (*Phytopathology, 34 (1944), No. 12, pp. 1069–1076, illus. 3*).—The new vascular disease reported as causing heavy local losses in sugar maple near Asheville, N. C., is characterized by thinning and ultimate death of foliage—usually within 2–4 yr. after onset of symptoms—accompanied by water-soak and radial gray and red streaks in the sapwood. The disease has been reproduced by inoculation with isolates morphologically indistinguishable from the common sap stain fungus on hardwood lumber earlier referred to *Endoconidiophora coerulescens* but recently recognized as distinct and renamed *E. virescens* (E. S. R., 91, p. 705).

Modification of procedure for differentiating the telia of Cronartium ribicola and C. occidentale, M. S. Cave (*Stain Technol., 19 (1944), No. 4, pp. 141–142*).—The ranges of these pine rusts now overlap in parts of the western United States, and on leaves of *Ribes* the telia are morphologically undistinguishable. Since one is under quarantine regulation and the object of a large-scale control program while the other is of little consequence, a reliable and rapid differential method was highly to be desired. The microchemical method of Acree and Goss (E. S. R., 78, p. 202) has proved successful, but when large numbers of tests are being made a shorter schedule would be advantageous; such a method—here described—is said to have given as satisfactory differentiation as the longer schedule.

ECONOMIC ZOOLOGY—ENTOMOLOGY

The natural history and behavior of the western chipmunk and the mantled ground squirrel, K. Gordon (*Corvallis: Oreg. State Col., 1943, pp. 104, illus. 15*).—A monographic study, including the taxonomy, description, distribution, biology, ecology, behavior, and information lacking or little known on the western chipmunks (*Eutamias*) and the mantled ground squirrels (*Citellus*) in western North America.

An investigation of Myxomatosis cuniculi with special reference to the possible use of the disease to control rabbit populations in Australia, L. B. Bull and M. W. Mules (*Jour. Council Sci. and Indus. Res. [Austral.], 17 (1944), No. 2, pp. 79–93*).—The virus of myxomatosis is highly pathogenic and lethal to the European rabbit, but is said not to cause disease in other animals. The general results of this study—details of which are presented, and especially those of the field experiments and field trials—show that the disease cannot be used with any promise of success in controlling rabbit populations under most natural conditions in Australia. It seems possible, however, that in some parts of the country under special conditions—including the abundant presence of insect vectors and absence of predatory animals—it could be used with some promise of temporary control.

The pine mouse in your orchard, L. Davis. (Univ. Tenn.). (*Tenn. State Hort. Soc. Proc., 38 (1943), pp. 48–50*).—A note on *Pitymys pinetorum* and its control.

Red squill as a raticide, D. D. Green (*Soap and Sanit. Chem., 20 (1944), No. 11, pp. 101–102, 133*).—A general discussion, including some of the newer developments such as the fortification of red squill powders weak in potency.

Red squill, L. R. Parkinson. (Mass. Expt. Sta.). (*Pests, 12 (1944), No. 11, pp. 26–28*).—Essentially noted from another source (E. S. R., 92, p. 234).

[Bird notes] (*Auk, 61 (1944), No. 4, pp. 640–643, 644–645, 650–651*).—The following brief notes are included: An Arizona Nest of the Coppery-Tailed Trogon [*Trogon ambiguus ambiguus*], by A. A. Allen (pp. 640–642) (Cornell Univ.); Food of White-Rumped Shrikes [*Lanius ludovicianus excubitorides*], by G. F. Knowlton and F. C. Harmston (pp. 642–643) (Utah Expt. Sta.).; Observation on the Food of the Bronzed Grackle [*Quiscalus versicolor*], by S. G. Ernst (pp. 644–645); European Widgeon [*Mareca penelope*] in Alabama, by H. M. Stevenson (p. 650); and European Widgeon in California, by M. F. Reece (pp. 650–651).

[Bird notes], L. E. Hicks. (Ohio State Univ.). (*Wilson Bul., 56 (1944), No. 3, pp. 169, 174*).—These include: The American Egret [*Casmerodius alba egretta*] Breeding in Ohio and Blue Grosbeak [*Guiraca c. caerulea*] Breeding in West Virginia.

Notes on some Virginia birds, C. E. Addy. (Va. Expt. Sta. et al.). (*Auk, 61 (1944), No. 4, pp. 580–583*).

Estudio bionómico de los pájaros nidófilos.—I, Oscinas: "Passer domesticus" L. [Bionomic study of nidophile birds.—I, Oscines: P. domesticus], P. I. Sala de Castellarnau (*Brotéria, 13 (1944), No. 2–3, pp. 75–87*).—On the ecology of the English sparrow.

semicarbazide—a fairly toxic stomach poison but also injurious to foliage. The 50 compounds found relatively nontoxic are listed by name only.

The toxicity of sulfur dioxide, acetone, and ethylene oxide alone and in combination, E. M. Swisher. (Ohio State Univ.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 690–693, illus. 3*).—The author reports the results of a series of laboratory tests designed and conducted in an attempt to gain a clearer understanding of joint toxic action and the methods of determining it. Since the test mixtures used were found to be within the category of similar joint action and to exhibit no evidence of synergism, no actual data were available for synergistic tests. Nevertheless, a clearer understanding of joint toxic action and the difference between similar and synergistic action is gained from a study of these tests. The term synergistic is often used loosely and incorrectly as applying to a type of toxic action which is in the category of either independent or similar joint action. Combinations which might exhibit similar or independent rather than synergistic action are believed to offer many more practical possibilities than synergistic combinations, since it seems that true synergism is rare. The manufacturer or consumer may not be concerned as to the type of action given by a mixture so long as the product offers an improvement over the components alone. To the toxicologist attempting to evaluate a mixture accurately, however, the type of toxic action exhibited is a significant factor, and it is urged that the present policy of loosely labeling any and all promising combinations as synergistic be discontinued. The details and methods used in this study are fully considered.

Relation of chemical constitution of some N-heterocyclic compounds to toxicity as fumigants, H. L. King and D. E. H. Frear. (Pa. Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 629–633, illus. 1*).—This investigation included tests of 13 pyridine derivatives as fumigants against a common red spider, *Tetranychus telarius* (L.), 28 against the large milkweed bug, and tests of 34 materials related to pyridine against the confused flour beetle. Emphasis was placed on a study of the relationship between toxicity and length, position, and type of side chain. It was evident for all tests that in a series of 2–*n*–alkyl-pyridines a pronounced peak of toxicity occurred at the propyl– or butyl–derivative. Alkyl pyridines with side chains in the 4–position proved more toxic than the 2–substituted isomers, and compounds with normal side chains were usually more toxic than the branched isomers. The two alkyl piperidines available were more toxic than the corresponding pyridines. The relative toxicities of the materials tested against red spiders showed a high degree of correlation with the action of the same compounds against the two insect species studied.

Comparative toxicities of copper hydroarsenate and copper hydroarsenate-arsenite mixtures, J. W. Apple and C. H. Richardson. (Iowa Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 666–671*).—The greatest susceptibility to these two new basic arsenicals among the insects tested was shown by the differential grasshopper, followed by Colorado potato beetle larvae, the imported cabbageworm, and the corn earworm. Copper hydroarsenate proved the more toxic to potato beetles but was less so against cabbageworms and the spotted cucumber beetle; there was no significant difference in these materials against grasshoppers. These new products were more effective against cabbageworms than calcium arsenate. All three had similar toxic effects on the grasshoppers, but calcium arsenate was definitely more toxic to potato beetle larvae and corn earworms. Against the spotted cucumber beetle, calcium arsenate was about as toxic as the arsenate-arsenite but more so than copper hydroarsenate. Lead arsenate was less effective than the new products on grasshoppers and cucumber beetles, but was more effective against potato beetle larvae and corn earworms. Against cabbageworms, the hydroarsenate-arsenite and lead arsenate had similar toxicity, and both were more toxic than the hydroarsenate. Paris green was the most toxic compound against all insects tested, but two special arsenicals—the reacted paris green-calcium arsenate product and cupric metaarsenate—as tested against two insects were found nearly as toxic as paris green. Tests with potato beetle larvae and corn earworms revealed a definite repellent effect of the new arsenicals, with the hydroarsenate-arsenite apparently the more effective in this respect. Tests of toxicity to plants in the laboratory indicated the new compounds to be less injurious to bean foliage than the other arsenicals.

The picric acid method for determining minute amounts of hydrocyanic acid in fumigated insects, W. B. SINCLAIR and R. C. RAMSEY. (Calif. Citrus Expt. Sta.). (*Hilgardia [California Sta.], 16 (1944), No. 6, pp. 291–300, illus. 4*).—This contribution reports the development of a micromethod for determining amounts of HCN in the range of 0.005–0.200 mg. The HCN is distilled with a microdistillation apparatus from the fumigated insects into Na_2CO_3. Picric acid is then added to the alkaline distillate, diluted to a definite volume, and heated in a water bath for development of color. Color intensity is determined with a photoelectric colorimeter. Directions are given for controlling factors affecting color development.

Electrostatic charge effects produced by insecticidal dusts, H. F. WILSON, R. J. JANES, and E. J. CAMPAU. (Univ. Wis.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 651–655, illus. 1*).—Through use of a method devised for recording the electrostatic charges of blown dust, a preliminary study of samples of some commercial powdered insecticides and fungicides showed that there is a variation in the capacity of different mineral combinations to produce such charges. The sign of charge for all the materials studied was positive. Some differences in dispersion apparently influenced by the degree of charge were also noted, though until a more complete study is made it cannot be said that they were significant from the standpoint of insect or plant disease control. Finely ground plant and animal tissues of a granular nature produced electrostatic charges; those produced by plant materials were affected by the average particle size. When powdered dusts producing electrostatic charges were blown through tubes made of different metals no noticeable change in sign of the dusts could be observed; when such dusts were blown against plants an induced charge opposite to that of the dust was imparted to the plant and carried for its full length.

Intimate blending of dust insecticides, T. B. DORRIS (*Soap and Sanit. Chem., 20 (1944), No. 11, pp. 111–117, illus. 3*).—A discussion of the methods and potential importance of intimate blending, "which is capable of transforming ordinary insecticide mixtures into products of streak-free uniformity."

More efficient control of the use of insecticides is urgently needed, J. E. ECKERT. (Univ. Calif.). (*Iowa State Apiarist Rpt., 1943, pp. 62–67*).—A general discussion of the subject, with particular reference to beekeeping.

Wheat flour as an adhesive for sprays, L. T. GRAHAM, R. M. SANDSTEDT, and H. D. TATE. (Nebr. Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 599–604*).—In tests of the tenacity of spray components applied as suspensions—using insoluble copper sulfate as spray component or indicator—wheat flour gave a significant increase in tenacity, but addition of lime proved superior to the flour alone. The optimum amount of lime was about 0.09–0.36 gm. to 3 l. of spray, smaller or larger quantities giving reduced values. Added acetic acid or NaOH improved tenacity little if at all. On a paraffin surface, soybean flour alone was better than wheat flour alone, but with added lime they were equally effective. On a cellulose-nitrate surface plus combination with lime, wheat flour was superior to soybean flour. Used with lime, the optimum quantity of wheat flour was about 8 oz. and of soybean flour 1 oz. or more to 100 gal. of spray. Hardness of water had little effect on tenacity when flour was used alone, but with lime the use of tap water in diluting the spray gave a markedly higher tenacity index than when distilled water was employed. Of the components of flour, gliadin was apparently the best adhesive. Spray tests on greenhouse-grown potato plants indicated that addition of flour alone increased the tenacity only slightly; flour plus lime did so markedly. The latter combination was significantly better than soybean flour alone or with lime; with added lime, the tenacity of soybean flour was increased only slightly if at all.

The use of oleic acid and aluminum sulfate to increase deposits of nicotine bentonite, C. C. ALEXANDER, C. C. CASSIL, F. P. DEAN, and E. J. NEWCOMER. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 610–617, illus. 1*).—Results of the tests reported indicate 1–5 dry-mix nicotine bentonite applied with mineral oil, oleic acid, and $Al_2(SO_4)_3$ to be as effective as lead arsenate against the codling moth in the Pacific Northwest. The amount of nicotine sulfate used in these sprays was half that used in tank-mix nicotine bentonite sprays. Washes for cleaning apples sprayed with lead arsenate removed the spray deposit satisfactorily at harvest. As used, 1–10 nicotine bentonite failed to control the codling moth. Until the amount of nicotine needed in sprays is reduced or the price of nicotine lowered, nicotine-bentonite sprays will not be as economical as lead arsenate against the codling moth in this area.

The protective value of asphalt laminated paper against certain insects, H. L. SWEETMAN and A. I. BOURNE. (Mass. State Col.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 605–609*).—A 2-ply asphalt laminated Kraft paper sealed with an asphalt-glue adhesive was found to offer considerable resistance to penetration by the brown-banded roach and by the American, Australian, and German cockroaches, by three species of thysanurans (silverfish, firebrat, and the four-lined silverfish *Ctenolepisma quadriseriata*), and some resistance to a subterranean termite, *Reticulitermes flavipes*. The termites and firebrat seemed most likely to penetrate the wrapping paper in the shortest time. The American cockroach and firebrat caused the most damage. A fungicide—Dowicide G—in the adhesive offered little protection against fungi in the environments; at 1-percent concentration it greatly reduced the attractiveness of the adhesive to roaches and thysanurans, but the firebrat and silverfish still fed extensively on the adhesive during a 7-day test. Termites tubed over but did not injure paper in contact with 0.3 and 1 percent of fungicide in the adhesive, but damaged paper in contact with weaker concentrations.

Insecticidal action of D. D. T., H. MARTIN and R. L. WAIN (*Nature [London], 154 (1944), No. 3912, pp. 512–513*).—A preliminary note on studies leading to a working hypothesis on the mode of action of DDT and its analogs which has enabled the prediction of insecticidal activity in related compounds.

Summary of toxicological studies of the insecticide DDT, 2,2-bis (p-chlorophenyl) 1,1,1-trichloroethane, J. H. DRAIZE, G. WOODARD, O. G. FITZHUGH, A. A. NELSON, R. B. SMITH, JR., and H. O. CALVERY (*Chem. and Engin. News, 22 (1944), No. 17, pp. 1503–1504*).

Drug aspects of DDT, A. J. COX (*Calif. Citrog., 30 (1944), No. 1, pp. 6, 22–23, 26–27*).—An address summarizing previous findings on the toxicology of DDT, with special reference to its direct effects on man and animals and the dangers from its use on plant products to be used as food.

The biology and control of the camel cricket Daihinia brevipes, F. E. WHITEHEAD and F. D. MINER. (Okla. A. and M. Col.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 573–581, illus. 5*).—*D. brevipes* Hald.—found in the Great Plains States from North Dakota to northern Texas—is reported from Oklahoma as injuring various crops, such as tomatoes, watermelons, cotton, and cowpeas, in the seedling stage and mostly in sandy areas. It feeds at night, spending the day in burrows. During 2 yr. of intensive study serious crop injury was not observed, but indications are that such may occur under some conditions. Winter is passed as a semiactive nymph in burrows; the adult stage is reached about May 1, and oviposition occurs throughout June. The eggs—laid in the soil surrounding the burrow—hatch in late September, and the nymphs dig their way to the surface. There is one generation a year. Nocturnal activity was not closely correlated with weather, and migration appeared rather limited. The burrows increased in depth from 3 in. in February to 1–5 ft. in June. The number of eggs averaged 26.8 in the soil around each burrow. The insect is general in feeding habits; besides growing plants, it was observed to feed on such material as dry sticks, weed seeds, rabbit pellets, and on other insects including its own species. Poison bran mash gave satisfactory experimental kills.

A new Sericothrips from Brazil (Thysanoptera: Thripidae), J. C. CRAWFORD. (U. S. D. A.). (*Ent. Soc. Wash. Proc., 46 (1944), No. 7, pp. 200–201*).—*S. sidae* n. sp.—host *Sida rhombifolia*—is described at this time because its name is needed in connection with a study of insect vectors of infectious chlorosis of malvaceous plants.

A review of the North American species of Linnaemya sens. lat. (Diptera: Tachinidae), A. R. BROOKS (*Canad. Ent., 76 (1944), No. 10, pp. 193–206, illus. 11*).—New taxonomy and keys to the adults and first-stage maggots of this group of parasitic flies are included.

New North American Tachinidae belonging to the genus Muscopteryx (Diptera), H. J. REINHARD. (Tex. Expt. Sta.). (*Ann. Ent. Soc. Amer., 37 (1944), No. 3, pp. 352–358*).—A taxonomic study of seven species of this genus of tachinid flies, of which six are described as new.

On the food relations of Eurygaster integriceps in the highland of Western Uzbekistan, K. V. ARNOLDI (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 43 (1944), No. 1, pp. 32–35*).—On the food plants of the adults and larvae of this species of shield-backed bug, with particular reference to forage crops of the grass family in this part of the U. S. S. R.

A new aphid on guayule and notes on other species of Cerosipha, E. O. ESSIG (*Hilgardia [California Sta.], 16 (1944), No. 4, pp. 177–184, illus. 6*).—A new species of aphid, *C. californica* Essig, collected on guayule, prune roots, and potatoes in California and on tomato in Waipaha, Oahu, Hawaii, is described. Keys are given to the known species of *Cerosipha,* and brief descriptions are included for *C. araliae-radicis* Strom, *C. forbesi* (Weed), *C. rubifolii* (Thomas), and *C. roripae* Palmer.

Notes on leafhoppers with descriptions (Homoptera: Cicadellidae), D. J. KNULL. (Ohio Sate Univ.). (*Ohio Jour. Sci., 44 (1944), No. 5, pp. 239–242, illus. 7*).—Includes new species of *Xestocephalus* and *Stirellus.*

A new genus (Tenucephalus) and species of Mexican leafhopper related to Parabolocratus, D. M. DELONG. (Ohio State Univ.). (*Ohio Jour. Sci., 44 (1944), No. 5, pp. 236–237, illus. 6*).

Descriptions of nine species of Aleuroplatus from eastern North America (Homoptera: Aleyrodidae), L. M. RUSSELL. (U .S. D. A.). (*Jour. Wash. Acad. Sci., 34 (1944), No. 10, pp. 333–341, illus. 13*).—The nine species of whiteflies here treated (seven new) are said to form a well-defined closely allied group which is apparently of actual or potential economic importance, since several species occur on plants of commercial value and one is a suspected vector of the blueberry stunt virus disease.

Bionomics and control of the nigra scale Saissetia nigra, R. H. SMITH (*Hilgardia [California Sta.], 16 (1944), No. 5, pp. 225–288, illus. 21*).—*S. nigra* Neitner is recorded from 161 species of plants in California and 148 species elsewhere in the world. Taxonomic descriptions are given of all stages. Establishment of this species in California was first reported in 1920, and in the period 1936–40 it was exceedingly prevalent on trees and shrubs in the coastal region. Only one generation occurs annually. The adult stage is reached in April, May, or June, and egg laying extends from about the middle of May until February. Little growth occurs during the summer, fall, and early winter months, but rapid growth begins in late winter. Reproduction is parthenogenetic. The average number of eggs per female is 628. Many predaceous enemies are mentioned. About 25 species of hymenopterous parasites are recorded from various parts of the world. A species of *Torulopsis* or *Rhodturla,* a symbiotic organism, is present in large numbers in all stages of the scale. In the period 1939–40 the scale became almost exterminated in southern California from causes ascribed to natural mortality. The author discusses the possibility that the near extermination of the scale may have been the result of a disease caused by a virus or a micro-organism. The parasite *Metaphycus helvolus* Comp. has been an important natural enemy since 1940. Light-medium oil spray, used at the rate of 1.5 to 2 gal. to 100 gal. of water and applied in late summer or early fall, has given satisfactory control.

A list of over 100 literature citations is appended.

A mariposa oriental das frutas Grapholita molesta (Busck), H. S. LEPAGE and M. FADIGAS, JR. (*Biológico, 10 (1944), No. 5, pp. 135–140, illus. 5*).—On the history, distribution, characteristics, biology, and control of the oriental fruit moth and the nature of the damage which it causes.

Susceptibility of Japanese beetle larvae to Bacillus popilliae, R. L. BEARD. (Conn. [New Haven] Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 702–708, illus. 2*).—The incidence of milky disease among third instar Japanese beetle larvae was found to be a probit response to the logarithm of spore concentration of *B. popilliae* injected parenterally. Similarly, when beetle grubs were reared in soil containing the organism the incidence of disease followed a probit response to the logarithm of the spore concentration. As judged by these two modes of infection the virulence of *B. popilliae* in causing milky disease of the larvae is far less than that of *B. larvae* in causing foulbrood of honeybee larvae. Spores of *B. popilliae* injected into the alimentary tract of beetle grubs failed to demonstrate a well-defined dosage effect, and the disease incidence was less than expected. Beetle grubs failing to take the disease after a parenteral injection of spores may be less susceptible to a second injection, indicating a kind of resistance; reduced potency of the spores may also act independently to cause less disease than expected. In one test, grubs failing to acquire milky disease after one exposure to contaminated soil failed to show any diminished susceptibility when given a second exposure. This apparent contradiction of other tests may have been due to the technic employed in detecting the disease.

The life history of Phyllophaga calceata and of P. micans, H. J. REINHARD. (Tex. Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 581–587*).—The history of a complete generation of the May beetles *P. calceata* (LeConte) and *P. micans* (Knoch) in Texas was about as follows: Maximum numbers of overwintering adults emerged during April, and eggs were commonly present during the latter part and throughout May. About 25 days were required for the eggs to hatch. The larvae fed through the summer and after molting twice attained full growth by September or October. Normally the mature grubs passed the winter and remained quiescent during the following spring and summer until after mid-July, when pupation began; the average duration of the larval stage was 413 days. Pupation began during the latter half of July, and pupae were commonly present during August and September. About 23 days were required in this stage for transformation to adults; these remained within the pupal cells throughout the following winter and emerged the next spring to complete a 2-yr. life cycle.

Toxicity of cryolite to Mexican bean beetle larvae, G. WENE and R. HANSBERRY. (Cornell Univ.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 656–659, illus. 4*).—In laboratory cage tests against larvae of this pest, cryolite sprays were highly toxic, though slow acting and repellent. First to third instar larvae were more susceptible than fourth instar larvae. To obtain high kills with the last, 3–4 days of feeding on heavy deposits seemed necessary; 2 days sufficed for the younger stages. Time-mortality lines plotted according to the methods of probits were convex curves instead of straight lines, and are considered to be shaped by the nature of the feeding rather than by that of the toxic action of ingested cryolite.

Wireworms and food production: A wireworm survey of England and Wales, 1939–1942 (*[Gt. Brit.] Min. Agr. and Fisheries Bul. 128 (1944), pp. 62+, illus. 8*).—This report takes up the technic of wireworm sampling, wireworm populations, and the influence of wireworms on the establishment and success of arable crops; these matters are followed by a discussion of the findings from the survey, with recommendations.

Observations on the biology and physiology of wireworms of the genus Agriotes Esch., A. C. EVANS (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 235–250, illus. 10*).—It is shown by studies of wireworms kept at a constant temperature of 15° C. for 3 yr. and at natural soil temperatures for 2 yr. that small individuals grow rapidly and molt frequently, but that large ones grow slowly or remain constant in weight and molt infrequently. A basic pattern to account for this decreasing frequency of molting is presented. Studied in detail throughout the season, definite peaks in feeding activity and molting frequency were observed; a suitable method for analyzing such activity was found by dividing the population into groups on a basis of the number of annual molts. Increase in dry weight gave a more valid estimate of growth than increase in fresh weight. The rate of growth was strongly influenced by the food; wheat and carrots, e. g., permitted rapid growth, grass and clover gave smaller growth, mustard and potato allowed the wireworm to maintain its weight, and flax actually caused a decrease in dry weight. In a field test, the type of crop grown after breaking up the old pasture had a distinct effect on the wireworm damage to the following cereal crop. Beans reduced the population to a level at which a very successful crop was grown, and better yields were also obtained after wheat and grass. The wireworm cuticle is permeable to water, and it is shown that in relation to soil moisture this insect may be regarded as an osmotic system. The pF (suction force) scale of soil moisture proved of value in expressing the soil-moisture relations of wireworms; they feed more actively in moist than in dry or wet soil.

A note on Lecontella cancellata Lec. (Coleoptera: Cleridae) in cells of the mud-daubing wasp, P. RAU (*Ent. News, 55 (1944), No. 8, p. 197*).—A note on this beetle as an example of a border-line species between predatism and parasitism, with the weight of evidence in favor of the latter.

Observations on Comperiella bifasciata, an endoparasite of diaspine coccids, S. E. FLANDERS. (Calif. Citrus Expt. Sta.). (*Ann. Ent. Soc. Amer., 37 (1944), No. 3, pp. 365–371, illus. 1*).—The encyrtid *C. bifasciata,* in its relation to the California red scale, consists of two host-determined races; one is able to reproduce for generations on this scale, whereas the other is unable to do so because of its low fecundity on this host. As shown by cross-breeding, the capacity to develop in the red scale is a maternal effect. The developmental rate of *C. bifasciata* during its first instar varied with the developmental condition of the host at the time of attack. The ♀ host proved susceptible to successful parasitism in all its instars; the ♂ host, only in the first instar. The parasite was not successful when it attacked the host in the second instar. Its minimum life cycle was 21 days at 80° F. The sexes were approximately equal in numbers. One or more crystalline rods in the midgut of the developing larva indicate a urinary function of the midgut.

The genus Lachnomyrmex, with the description of a second species (Hymenoptera: Formicidae), M. R. SMITH. (U. S. D. A.). (*Ent. Soc. Wash. Proc., 46 (1944), No. 8, pp. 225–228, illus. 2*).—On a new species of ant, *L. haskinsi,* from the Canal Zone.

Common spiders of Maryland, M. H. MUMA (*Baltimore: Nat. Hist. Soc. Md., 1943, pp. 173+, illus. 141*).—Following discussions of the general external anatomy of spiders, their ecology, taxonomy, and collection and preservation, the author of this semipopular manual takes up the individual species by families (with key), giving a description, pertinent comments, and the known Maryland distribution for each. A glossary and indexes to Latin and common names are provided.

Mites of the family Bdellidae, E. W. BAKER and J. W. BALOCK. (U. S. D. A.). (*Ent. Soc. Wash. Proc., 46 (1944), No. 7, pp. 176–184, illus. 29*).—This paper is the first of a series on this family of predaceous prostigmatic Acarina; 7 of the 10 species described are new.

The life history of the tick Ornithodoros coriaceus Koch (Argasidae), C. N. SMITH. (U. S. D. A.). (*Ann. Ent. Soc. Amer., 37 (1944), No. 3, pp. 325–335*).—Data are presented on the eggs, larvae, seven stages of the nymphs, and the adults of this tick.

Ixodes ozarkus n. sp. and Ornithodoros aquilae n. sp., with notes on O. talaje and O. kelleyi (Ixodoidea), R. A. COOLEY (*Jour. Parasitol., 30 (1944), No. 5, pp. 287–294, illus. 3*).—The two new species of ticks are described and the three species of *Ornithodoros* compared.

Relation of chemical constitution of some N-heterocyclic compounds to toxicity to Aphis rumicis, H. L. KING, D. E. H. FREAR, and L. E. DILLS. (Pa. Expt. Sta. et al.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 637–640, illus. 1*).—Pyridine and 36 related compounds were tested as contact insecticides against the bean aphid. In a series of 2–*n*–alkyl–pyridines, compounds with 5 or more C atoms in the side chain were much more toxic than those with short chains, toxicity increasing with the length of the substituent group. A series of 2–*n*–alkyl–6–methyl pyridines closely paralleled the results with the 2–*n*–alkyl–pyridines. A series of 4–*n*–alkyl–pyridines was more toxic than the corresponding 2–*n*–alkyl compounds. Normal or straight-chain alkyl compounds were generally more toxic than the branched chain isomers. Addition of an amino group to the pyridine nucleus increased the toxicity much more than that of a methyl group in the same position. Hydrogenation of 2 alkyl pyridines to the corresponding piperidines failed to increase their toxicity. Toxicity to plants generally paralleled aphicidal action.

Heliothis virescens as a pest of cotton, with notes on host plants in Peru, E. J. HAMBLETON. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5,, pp. 660–666*).—The tobacco budworm has long been known as a serious pest in the tobacco sections of Florida, Georgia, Alabama, and Louisiana, but only within the past 10 yr. have observations shown its increasing importance as a cotton pest. Thus far there is no evidence to justify the hypothesis of a distinct biological race of the insect as a possible explanation for its comparatively recent destructive occurrence on cotton. Possibly a better interpretation of the fact could be gained from studies in localities where the insect is a pest of cotton, in order to determine its food plants other than cotton, the ecology of the areas where cotton is cultivated, and the role natural enemies play in effecting changes over a period of years. Data are presented and discussed in detail regarding the occurrence of the pest on cotton in Brazil and Peru and its host plants in the latter country—some 18 species including such common crop plants as flax, tomato, beans, and squash being listed with accompanying notes.

Laboratory technique for testing insecticidal dusts for pea aphid control, C. E. DIETER, R. L. JANES, H. F. WILSON, and H. L. BURDICK. (Univ. Wis.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 646–651, illus. 2*).—Regardless of the technics in evaluating insecticides, considerable error may occur even with the greatest care in procedure. A method is presented which, with the needed equipment for testing insecticidal dusts against the pea aphid, has been found highly satisfactory over a 5-yr. period. Details are given for the production of plants for aphid rearing and testing, for rearing the aphids, for preparation of the dust mixtures, and for the apparatus and technic of applying them. The accuracy of the testing method is discussed and examined by analyses of variance.

Strength of rotenone dust mixtures and rate of application in pea aphid control, J. E. DUDLEY, Jr., and T. E. BRONSON. (U. S. D. A. coop. Wis. Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 643–646*).—Two years' field tests brought the following conclusions: With an oil-conditioned rotenone-bearing dust mixture, the quantity of rotenone applied per acre governs—within limits—the resulting kill. With as much as 0.3 lb. of rotenone applied per acre, it makes little difference whether a dust mixture of high rotenone content at a low rate or one with lower content at a higher rate is used. When, however, only 0.15 lb. or less of rotenone per acre is used, a dust mixture of high rotenone content at a low rate is preferable to one of low content at a high rate. A marked decrease in pea aphid kill occurs in an oil-conditioned dust mixture when the rotenone content is decreased from 0.375 to 0.25 percent or lower. It is concluded from 1943 results that when either 0.15 or 0.3 lb. of rotenone is applied per acre, a decrease in the rotenone content of the dust may be partially compensated for by an increase in the rate of application, but that this relationship fails to hold true when only 0.075 lb. of rotenone per acre is applied with dust mixtures of the rotenone contents used.

Effect of Empoasca solana on sugarbeets grown for seed, O. A. HILLS, V. E. ROMNEY, and K. B. MCKINNEY. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 698–702, illus. 2*).—Sugar beet seed production in outdoor cages at Phoenix, Ariz., was materially reduced by a small green leafhopper, *E. solana* DeL. There also seemed to be a tendency for this insect to cause slight increases in the proportion of small seeds, though in no case was there any appreciable reduction in their viability. These facts, together with observations on the plants involved and on the habitat of the insects under both field and cage conditions, led to the conclusion that this leafhopper feeds largely on the vegetative parts of the plants and that the damage attributable to it is mainly from devitalization of its host. In no case was there evidence of a diseased condition or toxic effect from infestation.

Two important wheat pests, F. R. PETHERBRIDGE and J. H. STAPLEY (*Agriculture, Jour. Min. Agr. [Gt. Brit.], 51 (1944), No. 7, pp. 320–324, illus. 1*).—On damage (1944) to winter wheat in England by the wheat bulb fly *Leptohylemyia coarctata* and the wheat shoot beetle *Helophorus nubilus.*

Studies of fluctuations in insect populations.—XI, The interrelationship of the wheat blossom midges and their host plant, H. F. BARNES and J. W. WEIL (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 231–234, illus. 2*).—According to studies amplifying previous findings on the wheat midges *Contarinia tritici* Kirby and *Sitodiplosis mosellana* Géhin (E. S. R., 86, p. 214; 88, p. 370), at date of wheat blossom midge emergence in an insectary some distance away from the growing wheat can give as reliable an estimate of the forwardness of the crop as field observation of the date of ear emergence. The percentage of grain attacked by these midges—which can be assessed by routine workers without special experience with wheat—can give an early and useful first estimate of the crop yield.

Uma lepidobroca da couve [A webworm infesting cabbage], O. MONTE (*Biológico, 10 (1944), No. 5, pp. 141–144, illus. 6*).—On injury to cabbage by larvae of the pyralid moth *Hellula phidilealis* Walker and on the biology and control of the pest.

Mercury substitutes for cabbage maggot control, L. E. Dills, D. E. H. Frear, and H. L. King. (Pa. Expt. Sta.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 640–642*).—Field tests on radishes were made with 36 different treatments with 22 materials, including several chlorinated hydrocarbons, N-heterocyclic compounds, and a number of miscellaneous new substances. The best safe material tested for early use was a calomel-bentonite dust; the best late treatment was with dichloroethyl ether. The smallest percentage of infestation with maggots followed use of a dormant tar oil and 2-ethyl-pyridine sulfate dust at 10 percent, but plant injury was very severe. Several of the other pyridine derivatives proved effective in control, but with considerable plant injury. Preliminary tests indicated that some of these treatments preventive of maggot damage but causing injury to radishes could be used safely on cabbages.

Treatment of unstaked tomato crops: Economic control of mite and caterpillars demonstrated, A. H. Friend (*Agr. Gaz. N. S. Wales, 55 (1944), No. 10, pp. 424–425*).—In the test reported (1944) payable returns were obtained from fall dusting with equal parts of sulfur and hydrated lime to control the tomato mite *Phyllocoptes lycopersici.* To take full advantage of this increased yield, growers are advised to apply lead arsenate for protection of the fruit from caterpillars, and also to control fungus diseases. This mite is said to have been the chief factor consistently tending to decrease yields of summer and later crops in New South Wales.

Effect of scraping and banding trees upon the numbers of transforming and hibernating codling moth larvae, H. Baker. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 624–628*).—In replicated plots in commercial orchards it was shown (1938–40) that estimates of the percentage of catch of larvae in bands varied widely according to the basis on which they were made; the one based on the number of larvae developing is believed to indicate more accurately than the others tried the actual extent of the effect of banding on codling moth populations. Under Missouri River Valley conditions, there was a very heavy mortality between the time the insect left the fruit as a mature maggot and the time when it emerged as a moth or entered hibernation. Nearly as many larvae transformed and developed into moths as entered hibernation on the check trees, more did so on the scraped trees, and still more—not counting those on the bands—on the trees that were both scraped and banded. Scraping—and to a greater extent when combined with banding—effected material reduction both in numbers of larvae developing into moths and in numbers entering hibernation. Of all larvae leaving the fruits during the 3 yr., 35.2 percent of those on the check trees developed into moths or entered hibernation, whereas 20.7 percent did so on the scraped trees and only 13.9 percent on those both scraped and banded. The effect of banding on moth emergence and larval hibernation was much greater than that indicated by the percentage of the larvae leaving the fruit and caught in bands. Transforming larvae were found to cocoon in largest numbers in the lower third of the trees and under bark, in crotches or forks of limbs, or in pruning or other scars.

A dust experiment for codling moth control in a heavy infestation, M. M. Barnes. (Cornell Univ.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 620–623*).—Three dusts—(1) 20 percent lead arsenate, 20 percent Black Leaf 155, and 60 percent Micronized Dusting Sulfur; (2) the same proportions of the first two, with a proprietary diluent; and (3) 20 percent lead arsenate, 10 percent Black Leaf 155, and 70 percent Micronized Dusting Sulfur—were applied in eight cover treatments to three Latin squares laid out in a relatively heavily infested orchard. In addition, all plots received two cover dusts of 20 percent lead arsenate and 80 percent Micronized Dusting Sulfur. Each application was from both sides and averaged 2 lb. 6 oz. per tree. Codling moth injury in the dusted plots was at 15–20 percent entrances, with about 30 percent stung fruit; in no case were differences between treatments significant; the figures for a representative untreated tree were about 58 and 17 percent, respectively. The results would indicate that a program of this type should be resorted to in similar infestations only if—from labor shortages or other conditions—it is not feasible to spray; in such cases a considerable reduction in damage may be expected from such a program. It is believed that an increase in the amount of dust per tree would result in improved control. None of the samples taken at harvest exceeded the domestic tolerance for residue of As_2O_3; this is thought largely attributable to the infrequency of dew when applications were made.

Repellency of pyrethrum extract and other materials to full-grown codling moth larvae, M. A. Yothers and F. W. Carlson. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 617–620*).—In tests conducted since 1936 on the lookout for a repellent against larvae searching for cocoon quarters, bands of corrugated paper impregnated with the test materials were placed half way around the trunks of apple trees and the repellent effects determined by comparing the numbers of larvae captured in contiguous treated and untreated bands at the end of 30, 60, and 90 days. Among some 250 formulas tried, best results followed the use of combinations of 5 percent pyrethrum extract with either 5 or 10 percent of cottonseed oil emulsified with blood albumin. Undiluted pyrethrum extract proved highly effective, but its action decreased with long exposure. Cottonseed oil undiluted was considerably less repellent, but its effects increased with longer exposure. Kerosene alone was neither repellent nor attractive and when used with pyrethrum extract reduced the effect of the latter. Dilutions of 1 percent dinitro-*o*-cresol—alone and with 10 or 20 percent cottonseed oil—appeared slightly attractive during a 30-day test but showed slight repellency over longer periods. Alone or plus cottonseed oil, nicotine sulfate (40 percent) at 1 percent dilution was at most only slightly repellent; stove oil at 10 percent was valueless.

Observations on the parasites of Cydia pomonella L. in southern France, F. J. Simmonds (*Sci. Agr., 25 (1944), No. 1, pp. 1–30, illus. 5*).—The species of parasites and predators attacking the various stages of the codling moth in southern France were reared and their biology was investigated. Experiments were set up to determine whether fruit in any particular part of a tree was more liable to attack by *Cydia* than another and whether at any part the degree of parasitism was higher. The influence of species of host tree on parasitism was likewise studied. The host preferences of one of the parasites, *Dibrachys cavus* Walk., were tested because of its peculiar behavior; it can be either ecto- or endo-parasitic, according to host. Secondary parasites are also considered. The degree of biological control is discussed, and recommendations are made as to which parasites should be shipped to Canada for codling moth control there.

Relation of mortality to amounts of hydrocyanic acid recovered from fumigated resistant and nonresistant citrus scale insects, D. L. Lindgren and W. B. Sinclair. (Calif. Citrus Expt. Sta.). (*Hilgardia [California Sta.], 16 (1944), No. 6, pp. 301–315, illus. 6*).—Resistance to fumigation with hydrocyanic acid gas (HCN) in the California red scale was first noted in 1914 and resistance in the black scale in 1915. Fumigation of nonresistant and resistant California red scale under laboratory conditions indicates that the resistant race, with the various concentrations and exposures tried, is more difficult to kill than the nonresistant. Any added increment of either concentration or exposure has a greater effect on the kill of the nonresistant than of the resistant red scale. A larger quantity of HCN is recovered from fumigated nonresistant than from fumigated resistant red scale. When red scale is killed by heat or lack of oxygen, and then fumigated, more HCN is recovered from the nonresistant than from the resistant race. With refumigated red scale previously killed by HCN fumigation but not dried up, more HCN is recovered from the resistant than from the nonresistant race. With red scale fumigated when dead and dried, equal amounts of HCN are recovered from the resistant and from the nonresistant race. More HCN is recovered from fumigated nonresistant than from fumigated resistant black scale.

More fumigation experiments: Absorption of hydrocyanic acid by resistant and nonresistant scales, D. L. Lindgren and W. B. Sinclair. (Calif. Citrus Expt. Sta.). (*Citrus Leaves, 24 (1944), No. 10, pp. 8–9, illus. 4*).

Absorption of HCN by resistant and non-resistant scale insects, D. L. Lindgren and W. B. Sinclair. (Calif. Citrus Expt. Sta.). (*Calif. Citrog., 29 (1944), No. 12, pp. 341, 356, illus. 4*).

Effect of soils, cover crops, and foliage on concentration of HCN in citrus fumigation, R. A. Fulton and R. L. Busbey. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 597–598, illus. 1*).—The loss of hydrocyanic acid gas through sorption by soils, cover crops, and citrus foliage proved negligible as compared with the probable initial loss through the tent fabric when the fumigant was released.

The citrus thrips, measures for its control, and their effect on other citrus pests, E. A. McGregor (*U. S. Dept. Agr. Cir. 708 (1944), pp. 12, illus. 7*).—This paper summarizes and brings up to date findings on the citrus thrips and its control. The influence of thrips control measures on other citrus pests is also discussed. Seven noteworthy illustrations supplement the text.

The bronze orange bug (Rhoecocoris sulciventris Stal.), a citrus pest of the North Coast, P. C. Hely (*Agr. Gaz. N. S. Wales, 55 (1944), No. 9, pp. 397–401, 406, illus. 4*).—This pest is reported to have caused injury to citrus trees in the area for many years and in 1943—following one of the severest winters on record—the populations reached enormous proportions, in some orchards practically ruining the crop as well as seriously weakening and defoliating the trees. Furthermore, an appreciable amount of injury and discomfort was caused to persons working among infested trees owing to the corrosive fluids ejected by the bugs which caused severe irritation to membranes and skin. Of some 50 materials tried against the pest, soft soap showed up to advantage as to both cost and effectiveness.

Two new aphids from rhododendron and related plants (Homoptera: Aphididae), A. N. Tissot and J. O. Pepper. (Fla. Expt. Sta. and Pa. State Col.). (*Fla. Ent., 27 (1944), No. 2, pp. 21–33, illus. 21*).—On *Amphorophora rhokalaza* and *A. kalmiaflora* n. spp.

The relation between host condition and attacks by the bronzed birch borer, R. F. Anderson. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 588–596, illus. 4*).—This borer is not a very aggressive subcortical feeder and can develop successfully only in extremely decadent trees. Data presented indicate that the adults are attracted to and attack the suppressed, girdled, or topped-and-felled quaking aspen and paper birch trees, those most decadent being most suited to attack. These were trees that had stopped producing radial increment. Decadent trees that were still growing in diameter (suppressed trees and portions of the stem above the girdle on recently girdled trees) were only slightly attackd. The evidence submitted shows that even the poorest of the growing trees were unsuited to development of the larvae; on the other hand, trees dead so long that the phloem tissues were brown also proved unsuited. The findings suggest that whenever this borer is found in dying trees it should not be considered the primary cause of death until all other possible factors have been evaluated.

Investigations of the flour beetles of the genus Tribolium.—III, A colour strain of T. castaneum (Hbst.), L. W. Miller (*Jour. Dept. Agr. Victoria, 42 (1944), No. 10, pp. 469–471*).—A continuation (E. S. R., 92, p. 246). Adults of this new strain—found in Victoria in 1943—are dark brownish-black to black, the normal color being reddish-brown. Crosses between the two strains revealed that the color is apparently due to a single factor. On a nutritive diet, larvae of the normal "red" strain developed more rapidly than those of the "black" strain; on a less nutritive diet the reverse was the case. It is suggested that this result may be due to differences in sensitivity to a B-vitamin deficiency, the normal red strain being the more sensitive.

Relation of chemical constitution of some N-heterocyclic compounds to toxicity against Tribolium confusum, H. L. King and D. E. H. Frear. (Pa. Expt. Sta. et al.). (*Jour Econ. Ent., 37 (1944), No. 5, pp. 634–637, illus. 1*).—Tests of 17 salts of various pyridine derivatives were made against adults of the confused flour beetle. Results with a series of alkyl pyridine sulfates indicated that salts with short side chains were more toxic than those with long ones. The toxicity of these compounds appeared due largely to the material ingested rather than to contact action. A series of alkyl pyridine copper chloride double salts seemed to be completely repellent to the beetles. Results with 3 other salts of 4-*n*-propyl-pyridine indicated that the picrate, salicylate, and the zinc chloride double salt were slightly toxic or partially repellent, or both.

Natural sources, habitats, and reservoirs of insects associated with stored food products, E. G. Linsley (*Hilgardia* [*California Sta.*], *16 (1944), No. 4, pp. 185–224*).—According to the author, stored-products insects share biological characteristics which have affected their wide distribution and made them pests. Apparently these insects tolerate more extreme conditions of temperature and humidity than many less widely distributed forms. Many can survive in foodstuffs with a moisture content far below the optimum. Further, man usually provides optimum conditions in buildings, warehouses, and food-storage units. Certain of these insects include in their diet the majority of dry food and drug products of plant and animal origin, exhibiting a wider food range than that generally attributed to most other insects. Nearly all the species reproduce almost continuously under favorable conditions and require no winter diapause. Adults are often long-lived and may reproduce over a period of years, and some of the most important species can survive for long periods without food, permitting transportation in the absence of suitable food. Finally, most of them are small-sized and can remain undetected until a large population has been built up. Several (Bruchidae, *Sitophilus* spp., *Sitotroga* spp.) naturally infest seeds and have become pests without evolution of food habits. Many (Cryptophagidae, Mycetophagidae, Lathridiidae, Acaridae) are actually fungus feeders and seek out molds and fungi in foodstuffs. In nature these species live under bark, in nests of birds, mammals, and insects, or in decomposing plant materials. Many general scavengers on dead plant materials will infest stored products—chiefly moths (phycitids, pyralids) but also anobiids and nitidulids. Scavengers or semipredators living under bark have also become pests—including Tenebrionidae (flour beetles, mealworms), Cucujidae, and Ostomatidae. Wood borers include Ptinidae, Anobiidae, Bostrichidae, and Scolytidae. Insect nests have contributed several of the Galleriidae, Phycitidae, Ptinidae, and Dermestidae. The pollen stored by bees may have influenced evolution of food habits and served as a bridge between zoophagy and phytophagy. Many species associated with stored food products are predators and parasites of other insects present. Of these, Histeridae, Corynetidae, and Anthocoridae are probably attracted to the products and habitat directly rather than by specific insects present. Primary natural reservoirs of stored food products pests are bark and decomposing wood; nests and food caches of other insects, especially bees, wasps, and ants; and nests of birds and rodents.

A list of 165 literature citations is appended.

Sulfur dioxide-acetone as a household fumigant, E. M. Swisher. (Ohio State Univ.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 694–697, illus. 1*).—The fault with SO_2 as a household fumigant is said to lie mainly in the ordinary methods of application. When combined with acetone it forms a liquid that is stable when confined but readily decomposes into its component parts on exposure to air under standard conditions. The molecular weight and 1 : 1 by volume ratios of SO_2-acetone were both found to be good household fumigants, are conveniently handled as liquids, and are less flammable than HCN. These mixtures of SO_2-acetone could be packaged conveniently and applied for the evolution of SO_2 in household and other fumigations. The new method of application greatly reduces or eliminates most of the objectionable qualities of SO_2, outmoding the practices of generating the gas on the job or the use of heavy returnable cylinders; it should promote the use of the compound, especially against bedbugs in dwellings.

Trichloracetonitrile as a fumigant, H. H. S. Bovingdon and F. P. Coyne (*Ann. Appl. Biol., 31 (1944), No. 3, pp. 255–259*).—In determinations of the reactions of this fumigant on various insects infesting stored products and houses, the toxicity was found to be increased by adding 10 percent or more of CO_2. In the fumigation of bulk-stored wheat trichloroacetonitrile compared favorably with ethylene oxide. Its phytocidal action on seed wheat at doses which might be used in practice was not serious and the vitamin B_1 and riboflavin contents of wheat were not affected, but it proved highly toxic to growing plants. The possibility of its use in fumigating dried fruit was demonstrated.

Persistence of D. D. T. in oil-bound water-paint, G. A. Campbell and T. F. West (*Nature [London], 154 (1944), No. 3912, p. 512*).—A preliminary note on tests demonstrating that oil-bound water paint incorporated with DDT was effective against houseflies and had not lost its insecticidal properties after 2 mo.

The persistence and termite resistance of creosote and its constituent fractions, P. J. A. Loseby and P. M. D. Krogh (*Jour. So. African Forestry Assoc., No. 11 (1944), pp. 26–32, illus. 2*).—When small blocks of *Pinus insignis* sapwood treated full-cell by submersion in a creosote of South African manufacture and in its constituent fractions were exposed to atmospheric conditions for 5.5 yr., the amount of creosote lost by evaporation and solution was 47 percent, whereas losses of its fractions varied from 91 percent for that distilling below 270° C. to none for the residue above 355°. The loss of creosote from treated wood blocks is compared with that from open dishes. A similar set of blocks was buried at the site of the International Termite Test at Pienaar's River, Transvaal; the fractions distilling above 315° appeared to give the greatest protection.

The influence of color and finish on the attractiveness of papers to thysanurans, H. L. Sweetman, F. E. Morse, and W. Wall. (Mass. State Col.). (*Pests, 12 (1944), No. 10, pp. 16, 18*).—The firebrat was found to be definitely attracted to certain colors of wallpaper—particularly orange—but not for feeding purposes by the color; green paper was not attractive. The whole-wheat paste powder used for sticking the paper proved an attractive food to thysanurans, but these insects did not penetrate the face of the paper because of the paste on the back. Certain wallpapers may attract them for feeding because of the paper proper, but much more frequently the adhering paste, the sizing, or the dye ingredients are the stimulating substances. A number of other types of paper—some of which lacked sizing—were more attractive to thysanurans than a wallpaper. Newspaper and a brown wrapping paper, however, offered little attraction as food and were good protecting materials when several layers thereof were tightly wrapped about articles likely to be damaged by this group of insects.

Mosquito survey activities at Camp Peary, Virginia, C. K. Dorsey (*Ann. Ent. Soc. Amer., 37 (1944), No. 3, pp. 376–387*).—For the type of survey conducted

(1943), each of the four methods of collecting adult mosquitoes—light traps, house traps, barrel traps, man—proved useful and each supplemented the others. When storage batteries must be used to operate light traps, the heavy duty type should be employed. The operation of light traps on bright moonlight nights failed to give an accurate indication of the mosquito population. For successful operation of barrel traps, it is essential that they be located in carefully selected sites and that they simulate as nearly as possible a hollow log. In collecting mosquitoes from man at night, satisfactory results were obtained by having the victim strip to the waist. Adult mosquitoes were most prevalent during June-July; it is believed that adverse (dry) weather condition in August 1943 caused them to be less numerous than usual during that month. The 1943 records indicated that the active breeding season in this locality begins in April and continues through October; these dates coincide very well with the 10-yr. average dates of killing frosts in spring (April 9) and fall (October 31) for this region. By planning mosquito control activities accordingly, optimum results can be expected. In general, the distribution of mosquito larvae was similar to that observed by other workers. The presence of one or more species of larvae definitely associated with larvae of disease-carrying mosquitos, in particular types of breeding locations, can be recognized as an indication of the necessity for mosquito (species) control. The data presented are not regarded as finally conclusive, since they are the results of only one season's activities.

The rearing of sterile adult Anopheles, M. A. BARBER (*Pub. Health Rpts. [U. S.], 59 (1944), No. 42, pp. 1384–1387*).—The method involves culture of these mosquitoes in workable quantities in a liver extract-yeast medium in the presence of a single species of ciliate.

Control of Aedes aegypti in Savannah, C. A. HENDERSON (*Pub. Health Rpts. [U. S.], 59 (1944), No. 41, pp. 1350–1352*).—The results of an inspection and follow-up campaign, together with an intensive educational program, proved so successful that it is believed a permanent control program is economically sound and should be continued after the present emergency has passed. The general improvement of sanitary conditions alone proved well worth the cost involved.

Studies on mosquitoes from the Philippine Islands and Australasia (Diptera: Culicidae), A. STONE and R. M. BOHART. (U. S. D. A. et al.). (*Ent. Soc. Wash. Proc., 46 (1944), No. 8, pp. 205–225, illus. 14*).—"This paper is presented to make the names of eight new species and two new subgenera available for those engaged in mosquito work in the Pacific area, and to point out characters that will separate species which have been confused in the past." Identification keys are provided.

New culicine mosquitoes from the Philippine Islands (Diptera: Culicidae, R. M. BOHART and S. D. FARNER (*Biol. Soc. Wash. Proc., 57 (1944), pp. 69–73, illus. 15*).—Four new species are described.

The relation of particle size to the effectiveness of paris green used in airplane dusting for mosquito control, R. L. METCALF and A. D. HESS (*Pub. Health Rpts. [U. S.], 59 (1944), No. 45, pp. 1458–1465, illus. 3*).—Previous studies have shown that in airplane dusting against larvae of the common malaria mosquito an average of about 75 percent of the paris green dust drifts away from the treatment area because of fine particle size. Laboratory tests indicated that the average maximum diameter of particles ingested by first to fourth instar larvea were 29μ, 51μ, 68μ, and 106μ, respectively. The median lethal dose of paris green to fourth instar larvae was 0.05 mg. per gram of body weight, or the equivalent of a particle about 40μ in diameter. Toxicity tests with fourth instar larvae showed no significant difference between paris green particles 1μ or less in diameter and those 50μ–75μ in diameter. A special paris green having a particle size analysis of 84 percent by weight with 20μ–50μ in diameter was compared by airplane dusting with standard paris green which had 48 percent by weight in this size range. Use of the coarse dust resulted in a 60 percent increase in the amount of dust reaching the treatment area. Field tests with the coarse dust under average conditions gave a larval kill of 90–100 percent. Manufacturing costs for the large dust were no greater than for the standard. It is therefore believed that specifications for paris green to be used in airplane dusting should be revised to encourage production of a material with more desirable particle size composition.

Observations on the biology of the stablefly in Florida, S. W. SIMMONS. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 680–686*).—The minimum incubation period of eggs tested at 28° C. was 19 hr. and the maximum 120 hr.; the mean minimum was 39.65 hr., the mean maximum 65.1 hr., and the calculated arithmetic-mean incubation period 52.3 hr. In Richardson's medium at 30°, first instars were found at 1–80 hr., second instars at 44–144 hr., and third instars at 97 hr. up to pupation. The developmental period was longer during midwinter, even at summer temperatures. In a fresh bay-grass medium development was as rapid as in Richardson's medium. The mean minimum pupal period was 6.55 days at 28°–32° and the longest period was encountered during midwinter; during April–June the mean minimum was only 5.8 days. Some adult flies captured in nature and fed on citrated beef blood lived as long as 47 days, but most of them died earlier. The minimum pre-oviposition period found was 8 days; the mean, 10.6 days. Feeding stableflies often punctured the skin of their host several times before drawing blood; once blood was found, engorgement occurred in 1.5–8 min. Tests at Sarasota, Fla., showed that under semifold conditions this fly fed on man more readily in the morning and late afternoon and became sluggish during the midday heat. Bay grass isolated for 7 days before oviposition was permitted produced less than half as many adult flies as when infested green. Grass initially exposed to flies after 14 days' isolation produced only about 20 percent as many flies as when exposed green; after 21 days' isolation, emergence dropped to 3.21 percent. Thus uninfested grass as old as 21 days need not be treated to control subsequent fly breeding. Third instars overwintered in peanut litter in northwestern Florida. Slow development occurred throughout the winter and large numbers of flies emerged during warm periods. The cycle from egg to adult may be as short as 13 days or—under adverse conditions—it may require several months.

The repellency of a pyrethrum-thiocyanate oil spray to flies attacking cattle, D. E. HOWELL and F. A. FENTON. (Okla. A. and M. Col. et al.). (*Jour. Ent., 37 (1944), No. 5, pp. 677–680, illus. 2*).—Lethane— an oil base cattle spray with 6 percent toxicants including pyrethrum and two grades of a thiocyanate—applied to cows at 0.5, 1, and 2 cc. per 3.23 sq. ft. of body surface was repellent to the horn fly up to 10.5 hr. after spraying. Similar application rates were less repellent to the stablefly, both as to amount and duration; little repellency against this pest was noted after 4–5 hr. following treatment. As the time after spraying increased, the amount of repellency to both pests decreased. In parallel tests, 2 cc. of spray per 3.23 sq. ft. of surface was more repellent to the horn fly than 0.5 cc. for 7 hr. after the morning treatment; at other times no significant differences were noted. The heavier application was more repellent to the stablefly for only 4 hr. after the morning spraying and for 2 hr. after the evening spraying. The horn fly infestation was greater in the morning than during the afternoon; the stablefly infestation was greatest in the evening.

Screwworm survey of the Southeastern States in 1943, W. G. BRUCE. (U. S. D. A.). (*Jour. Econ. Ent., 37 (1944), No. 5, pp. 687–689, illus. 1*).—This survey revealed widespread infestation in Florida, Georgia, and Alabama, reaching outbreak proportions in peninsular Florida and southern Georgia with considerable loss of livestock. Favorable climatic conditions, together with the shortage of experienced farm labor and unavailability of effective remedies, contributed to the rapid build-up and spread of the pest. The incidence and relative abundance of screwworms throughout the Southeastern States were determined, and a fair estimate was obtained of needed critical insecticides. Furthermore, the survey insured proper distribution and conservation of these insecticides and aided in reducing infestations and attendant losses.

The cattle grub problem in North Dakota, J. A. MUNRO (*North Dakota Sta. Bimo. Bul., 7 (1944), No. 1, pp. 7–9, illus. 1*).—A practical account.

The Triatominae of North and Central America and the West Indies and their public health significance, R. L. USINGER (*U. S. Pub. Health Serv., Pub. Health Bul. 288 (1944), pp. 83+, illus. 64*).—This monographic study treats of the history of triatomine bugs and of their relation to Chagas' disease (including other vectors), biology, host relations, geographic distribution, and systematics. A six and one-half page bibliography and a systematic index are included.

Food habits of several species of poultry lice with special reference to blood consumption, C. M. CRUTCHFIELD and H. HIXSON. (Univ. Fla.). (*Fla. Ent., 26 (1943), No. 4, pp. 63–66*).—The barbs and barbules of feathers and blood were found to comprise the food of the chicken body louse as well as of a species of the genus hitherto unrecognized as a poultry pest in the United States. These species obtain blood by gnawing through the epidermis and rupturing the quill of pin feathers. The diet of the shaft louse *Menopon gallinae* consists of barbs and barbules; that of the wing louse *Lipeurus caponis,* of hooklets of the flight feathers and occasionally barbs and barbules. The large chicken louse and the fluff louse feed largely on barbs and to some extent on barbules.

Uses of DDT on the poultry farm, D. O. WOLFENBARGER and E. HOFFMANN. (Del. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 545–546*).—Spraying the ceilings and walls of a poultry house resulted in striking control of the housefly. In trials of phenothiazine, thiourea, borax, and DDT as larvicides against the housefly and a fly identified as *Themira putris* (L.), DDT proved equal to the first and superior to the others, reducing the number of flies emerging by 90 percent over the untreated control.

Concerning colony temperatures, V. G. MILUM (*Iowa State Apiarist Rpt., 1943, pp. 57–61, illus. 1*).—A general discussion of honeybee colony temperatures—the proper limits and means of obtaining them—on the basis of the author's experimental work and with reference to studies by others.

Life of bees in winter, M. H. HAYDAK. (Minn. Expt. Sta.). (*Amer. Bee Jour., 84 (1944), No. 10, p. 346*).—The author briefly summarizes his observations on the life of honeybees in winter, since any information along this line has a very important bearing on the problem of wintering; "the more we know about this life, the easier it will be for us to help the bees go through the hardest period of their fight for existence with the smallest loss."

Our winter problems, E. J. ANDERSON. (Pa. Expt. Sta.). (*Gleanings Bee Cult., 72 (1944), No. 10, pp. 433–435, 467, illus. 3*).—Factors having a direct bearing on the ability of a colony of bees to survive are not only many but are complicated by the fact that each winter presents a different combination of conditions. Research work in Pennsylvania emphasizes the value of the following recommendations: Use only the best acclimated stock, winter the bees on a large amount of good quality food, pack the bees in colder climates, provide wind protection the year around, give each hive a top entrance, and use good beekeeping practices in fall and spring.

The food of the honeybee, M. H. HAYDAK. (Minn. Expt. Sta.). (*Iowa State Apiarist Rpt., 1943, pp. 68–72*).—An address presenting the present status of nutrition in the honeybee, based on studies by the author and others.

The chemical composition and nutritional value of pollens collected by bees, A. E. Vivino and L. S. Palmer. (Minn. Expt. Sta.). (*Arch. Biochem., 4 (1944), No. 2, pp. 129–136*).—Pollens collected by honeybees from dandelion, certain fruits, clovers, and fall flowers were found to possess high nutritive values. The concentrations of Ca, P, Mg, Fe, and Cu compared favorably with those of a number of plant foods, the Cu content being exceptionally high. The pollens proved to be good sources of pantothenic acid, niacin, thiamine, riboflavin, and ascorbic acid and also contained small amounts of vitamins E and D. The water-soluble vitamin concentrations of bee-collected pollens were as high as in a number of the better food sources of these respective factors; vitamins K and A were absent. Pollens collected by bees from the above sources contained an abundance of carotenoids and flavones; anthocyanins and chlorophylls were absent. The mean protein content of the bee-collected pollens studied compared favorably with that of common beans, peas, and lentils. When the ether-extracted mixed pollens were fed to rats as the sole source of protein at about a 22-percent level—the diet otherwise being complete—indications were that certain dietary indispensable amino acids—notably tryptophan and methionine (or cystine)—were not present in optimum amounts for their normal growth.

The possibility of making red clover a satisfactory source of nectar, J. N. Martin. (Iowa State Col.). (*Iowa State Apiarist Rpt., 1943, pp. 48–50, illus. 1*).—Although red clover depends on insects for pollination, the well-known barrier of flower tube length that puts the nectar beyond the reach of honeybees is the one feature preventing it from being on a par with alsike and white clovers for bee pasture. Honeybees were found to frequent short-flowered strains of red clover much more freely than the common strains. Studies over a period of years by the Iowa Experiment Station indicated that there are at hand in that State suitable short-flowered strains; it only remains to select and isolate them.

Honeybees increase clover seed production 15 times. (Ohio State Univ.). (*Iowa State Apiarist Rpt., 1943, pp. 51–53*).—On the basis of experimental results, it is recommended that farmers located near honeybee colonies make a special effort to grow legume seed. Those wishing to grow clover seed but needing honeybees near their fields may be able to induce commercial beekeepers to supply the bees by offering free apiary sites. Farmers are encouraged to own as large a number of colonies as they can profitably operate.

Honeybee pollination and fruit production, R. L. Parker. (Kans. State Col.). (*Iowa State Apiarist Rpt., 1943, pp. 54–56*).

La polinizacion de los frutales por la abeja [Pollinization of fruit trees by bees], F. M. Croce ([*Argentina*] *Min. Econ., Obras Pub. y Riego, Dir. Indus. y Fomento Agr. Bol. 28 (1942), pp. 77, illus. 19*).

ANIMAL PRODUCTION

Livestock improvement in China, R. W. Phillips (*Chungking: Min. Agr. and Forestry, 1944, pp. 160+, illus. 11*).—The three main divisions of this report cover (1) existing types, conditions, and practices, (2) methods of breeding for improvement, and (3) organizations best adapted to livestock improvement in China.

Smoked meats, II, III (*Canad. Jour. Res., 22 (1944), No. 5, Sect. F, pp. 97–106, illus. 1; pp. 107–118*).—A continuation of the series (E. S. R., 88, p. 516).

II. *Development of rancidity in smoked and unsmoked Wiltshire bacon during storage,* W. H. White.—The relative effects of smoking bacon on spoilage were investigated by smoking one-half of four bacons stored at 0°, 15°, 30°, and 45° F., with the other half stored at these temperatures without smoking, as in previous studies in this series. These results showed that smoked bacon may be satisfactorily stored for at least 2 mo. at 0°–30°, whereas unsmoked bacon was usually rancid after 1 mo., but spoilage due to the formation of excessive quantities of free fatty acids was of little importance. The effect of size of the piece smoked was investigated by making studies of the peroxide oxygen formation in the fat of the cuts of whole backs of smoked and unsmoked carcasses, each back of eight hogs being divided into six pieces, one-half of the backs smoked and the other half unsmoked. Peroxide oxygen determinations were made up to 98 days. The differences at various storage temperatures were small, but it was evident that greater peroxide oxygen formation occurred at the higher temperatures of storage. The greatest increase in free fatty acid formation occurred between 21 and 42 days' storage.

III. *Effect of maturation period on quality,* W. H. White, A. H. Woodcock, and N. E. Gibbons.—Maturation periods of 1–25.5 days at 30° prior to smoking at 140° showed that no consistent effects were apparent in flavor tests, surface bacterial growth, peroxide oxygen formation in the fat, and changes in color and color stability of the lean meat during storage periods at 30°. These differences were usually small and showed no consistent trend. The maturation period of 10–15 days seemed most suitable.

Chewings fescue seed as a feedstuff, D. WHITSON, N. R. ELLIS, and C. A. CABELL. (U. S. D. A.). (*Poultry Sci., 23 (1944), No. 6, pp. 544–545*).—Similar gains and gains per unit of feed consumed were produced by chicks on a controlled wartime ration and rations which consisted of 30 percent ground Chewings fescue seeds or 30 percent oats to 4 weeks of age. Satisfactory growth and no abnormalities occurred in rats on the Chewings fescue ration.

Commercial feeding stuffs—report on inspection, 1943, E. M. BAILEY (*Connecticut [New Haven] Sta. Bul. 480 (1944), pp. 143–230*).—The usual report (E. S. R., 90, p. 817) of the guaranteed and found analyses of 846 samples of feeding stuffs, including 42 samples of vitamin D carriers officially examined and 73 biological specimens examined for the presence of toxic materials in 1943.

The cattle of Britain, F. H. GARNER (*London and New York: Longmans, Green & Co., 1944, pp. 158, illus. 60*).—An account is given of the development of the cattle industry and its importance in Great Britain, with descriptions of various dairy, beef, and dual-purpose breeds. Financial aspects and the effects of the war on the cattle industry are discussed.

The Iberia heat tolerance test for cattle, A. O. RHOAD. (U. S. D. A.). (*Trop. Agr. [Trinidad], 21 (1944), No. 9, pp. 162–164*).—Data on the body temperature and pulse rate of 198 cattle placed in the sun shortly after sunrise and kept there throughout the day showed the effects of solar radiation on heat production in the cattle. Environmental conditions such as temperature were recorded. The cattle subjected to the solar radiation represented grades and purebreds of the Brahman, Angus, Santa Gertrudis, and Africander cattle. The adaptability coefficient devised as 100 — [10 (*BT* — 101.0], in which *BT* is the average body temperature obtained under the conditions of the experiment, served to indicate the ability of the animal to withstand the heat. Purebred Brahmans had the highest heat tolerance, with a coefficient of 89. Both the ½ Brahman × ½ Angus and the ⅜ Brahman × ⅝ Angus had a coefficient of 84. The respiration rate of the halfbreds was only 55 per minute, as contrasted with 61 by the ⅜ Brahman × ⅝ Angus; therefore the former cross was considered the more heat-tolerant.

The value of distillers' rye dried grains in the wintering rations for pregnant ewes, 1939–40—1940–41, J. B. OUTHOUSE, F. H. LEINBACH, and D. MEADE (*Maryland Sta. Bul. A32 (1944), pp. 10+*).—In two experiments with pregnant Hampshire ewes, distillers' rye grains, which were satisfactorily used for steers (E. S. R., 89, p. 469), did not give satisfactory results when substituted for shelled corn or for shelled corn and part of the clover-light timothy mixed hay used in these trials. The winter feeding periods lasted from November 1, 1939, to May 9, 1940, and from November 21, 1940, to April 10, 1941. The ewes were divided into three uniform lots, with all ewes shifted to different lots in the second trial. The ewes maintained their weights until lambing, but on distillers' rye grains deaths occurred more frequently among ewes that lambed. Pregnant and lactating ewes were more seriously affected by the nutritional deficiencies than were growing and fattening ewes which were not pregnant. There was an average of three deaths in the lot receiving distillers' rye grains in place of shelled corn and part of the clover-timothy hay, with an average of 1.5 deaths in the lot receiving distillers' rye grains in place of all of the shelled corn. The average final weights on these rations were also less than on shelled corn, cottonseed meal, mixed hay, and corn silage.

Cria de cerdos [Swine production], P. Aragón Leiva (*México: Ediciones Agr. Trucco, 1942, pp. 319, illus. 46*).—A comprehensive book on swine breeds and breeding, feeding, management, sanitation, diseases and parasites, and the processing of hog products.

Urine excretion by boars, W. W. Green. (Minn. Expt. Sta.). (*Amer. Jour. Vet. Res., 5 (1944), No. 17, pp. 337–340*).—Urine samples from boars of different ages from 10 to 76 weeks ranged from 0 to 15,600 cc. and averaged 4,287 cc. for 48 hr. The amounts of urine seemed to be associated more with age than with season. There were significant differences between inbred lines in the amount of urine secreted in a crate specially prepared for catching it.

Riboflavin deficiency in swine, with special reference to the occurrence of cataracts, M. M. Wintrobe, W. Buschke, R. H. Follis, Jr., and S. Humphreys. (U. S. D. A. et al.). (*Bul. Johns Hopkins Hosp., 75 (1944), No. 2, pp. 102–114, illus. 3*).—Following methods employed in previous investigations of components of vitamin B in the pig (E. S. R., 88, p. 799), signs of nutritional deficiency became apparent within 2–3 weeks in three pigs on a ration of vitamin-free casein, sucrose, lard, and a complete mineral mixture to which were added crystalline B vitamins—thiamine hydrochloride, nicotinic acid, pyridoxine hydrochloride, choline chloride, calcium pantothenate, inositol, and *p*-aminobenzoic acid. The animals failed to gain, their gait was unusual, they lost their tidy appearance, the hair coat became rough, dry, and thin, and there was a scaling and scabby formation of the skin. Lens opacities and other eye abnormalities were apparent in three pigs at ages varying from 112 to 156 days when riboflavin-deficient rations were fed. Litter mates receiving the same ration supplemented with riboflavin but no nicotinic acid exhibited no eye abnormality. Only one eye change was noted in 21 comparable pigs on standard rations. No lens opacity was found in 178 eyes of pigs killed in a local abattoir.

The nutritional requirements of the dog, L. Michaud and C. A. Elvehjem. (Wis. Expt. Sta.). (*North Amer. Vet., 25 (1944), No. 11, pp. 657–666*).—The requirements of the dog are discussed for the various carbohydrates, proteins, fat, minerals, and vitamins.

The minimum temperature for embryonic development in the domestic fowl (Gallus domesticus), E. M. Funk and H. V. Biellier. (Mo. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 598–540, illus. 1*).—Fresh-laid eggs from mated and unmated pens of White Leghorn hens, stored at variable temperatures, showed no development in fertile eggs below 76° ± 0.5° F. Blood rings did not develop at 80°.

The effect of artificial light on chicks brooded during hot weather, B. W. Heywang. (U. S. D. A.). (*Poultry Sci., 23 (1944), No. 6, pp. 481–485*).—Since the slow growth of chicks brooded in hot weather noted by Kempster and Parker (E. S. R., 76, p. 676) may be due to reduced feed consumption, data were obtained from six experiments at the U. S. Southwest Poultry Experiment Station, Glendale, Ariz., in which groups of Single-Comb White Leghorn or Rhode Island Red chicks were subjected to artificial light from midnight to daylight in the first experiment, all-night lighting in the second experiment, and all-night or midnight-to-daylight lighting in the remaining experiments, with some groups receiving no light in each experiment. In one experiment of 10 weeks' duration and the others of 12 weeks, chicks receiving artificial light weighed more and had eaten more feed than chicks receiving no artificial light. However, there was no appreciable increase in feed consumption and live weight from chicks receiving artificial light all night instead of from midnight to daylight. The pullets receiving artificial light all night or from midnight to daylight weighed more when they were 16, 20, and 24 weeks old than those receiving no artificial light, but the weights of the pullets receiving artificial light all night were slightly less than those of pullets receiving artificial light from midnight to daylight. These differences had little or no effect on the age at first egg or the egg weight.

Relative body depth an exciting cause for development of keel bursae in chickens, S. Bird (*Sci. Agr., 24 (1944), No. 12, pp. 591–599, illus. 2*).—Study of the influence of the relative weight and pressure on the roost in the development of keel bursae in chickens showed that the incidence and severity in the fowl was largely dependent on the magnitude of the pressure and depth through the pectoral region relative to body weight. Crooked keels decreased the incidence and severity of the keel bursae by reducing the relative depth of the bird. Variations in the body weight from year to year caused variations in the incidence of this abnormality. Evidently keel bursae afford protection against more serious injury. It appears that freedom from bursae could be expected only in rapidly growing families of inherited shallowness of body. The relation of the bursae arbitrarily graded to the body weight in Barred Plymouth Rocks was ascertained in 1942 for 120 cockerels at 26 weeks of age and in 1943 for 99 males.

A note by V. E. Hollinsworth on measuring equipment, developed especially for measuring the pressure that a bird may exert through its keel when roosting, is included.

Protein in poultry nutrition, D. C. Hill (*Sci. Agr., 24 (1944), No. 12, pp. 551–590*).—A comprehensive review is presented of the literature on protein nutrition and amino acid requirements of chicks for growth and of hens for egg production and hatchability. The effects of plant and animal proteins and the role of each of the amino acids are discussed at considerable length. Protein requirements of turkeys, ducks, and pigeons, pheasants, and quail are taken up in separate parts of the article. A bibliography of 269 references on proteins for these classes of poultry is presented.

Lactalbumin as a protein supplement for growing chickens, W. H. Ott and R. V. Boucher. (Pa. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 497–506*).—Investigations of the growth-promoting properties of commercial lactalbumin in different combinations with meat scrap and with soybean meal were reported in six experiments.

In the first experiment the highest rate of growth and the highest feed efficiency were produced at 8 weeks of age on a ration containing 15 percent of lactalbumin with 5 percent of meat scrap. This experiment was conducted in lots of 6–9 Single-Comb White Leghorn chicks of both sexes, with 0, 5, 10, 15, and 20 percent of lactalbumin and 20, 15, 10, 5, and 0 percent of meat scrap, respectively.

The second experiment was conducted similarly to the first with Barred Rock chicks with lactalbumin of a lower protein content. Sufficient amounts of lactalbumin and meat scrap were included in these rations to supply a total of 9 lb. of crude protein per 100 lb. of ration. The results were similar to those in the first experiment. Growth of both sexes was higher with lactalbumin as the sole protein concentrate than with meat scrap alone. Mutually supplementary action between lactalbumin and meat scrap was again evident.

In the third experiment, sexed Barred Rock chicks were used for comparing ratios of lactalbumin protein to meet scrap protein from 65:35 to 100:0. The highest growth was promoted by lactalbumin protein to meet scrap protein at ratios of 80:20 and 90:10, emphasizing the curvilinear relationship in females. The highest rate of growth to 8 weeks of age was produced with a ratio of 75:25 on lactalbumin to meat scrap proteins.

The fourth experiment was similarly conducted with a total of 18 percent protein in the ration, again using Barred Rock chicks. Lactalbumin promoted a higher and more efficient growth rate of both sexes than did meat scrap. The high mutually supplementary action was produced when lactalbumin supplied 62.5 to 75 percent of the animal protein. Highest growth of males occurred with a ratio of lactalbumin to meat scrap protein of 75:25, but a ratio of 62.5:37.5 promoted maximum growth in females.

The fifth experiment involved different combinations of lactalbumin and soybean oil meal for Barred Rock chicks. Here the two sexes behaved differently as males increased in growth with increasing proportions of lactalbumin, but in females growth appeared to decrease with greater amounts of lactalbumin.

In the sixth experiment, body weights of both sexes were greatest with the larger amounts of lactalbumin with soybean meal, thus not supporting a mutually supplementary action between the two proteins. In the tests with lactalbumin and meat scrap, 2.4 percent of the chicks were affected with perosis, whereas in the tests of lactalbumin and soybean meal 3.3 percent of the chicks developed perosis.

In these studies there were used 75 Single-Comb White Leghorn and 514 Barred Rock chicks, on which growth was ascertained to 8 weeks of age.

Beef blood proteins in chick diets, C. R. GRAU and H. J. ALMQUIST. (Univ. Calif.). (*Poultry Sci., 23 (1944), No. 6, pp. 486–490*).—When blood proteins were used separately as protein supplements to a ration of wheat bran, wheat, corn, alfalfa, brewers' yeast, crude soybean oil, fish oil, and minerals, the serum and fibrin fractions were far superior to the blood-cell fraction (E. S. R., 90, p. 88). Autoclaving the blood cells did not improve them, nor was the growth bettered by additions of arginine, cystine, threonine, methionine, or tryptophan when fed alone or in combination, but the cell fraction supported growth when supplemented by pure isoleucine, which seemed to be an essential amino acid for the chick and a necessary addition to the blood-cell fraction. Satisfactory growth was produced with 15 or 20 percent protein rations of mixtures of blood-cell protein and corn gluten meal 1 : 2. Gains nearly equal to those with sardine meal were produced when this mixture of corn gluten meal and blood cells furnished 60 percent of the total protein present in the 15 or 20 percent protein rations. Increased growth rate was produced with isoleucine, but not with leucine. Approximate maximum supplementation occurred with 2 parts of blood-cell protein to 4 parts of corn-gluten-meal protein. The studies were conducted in 5 experiments with tests of 15 or 20 days' duration and a total of 20 lots of 4, 5, 10, or 12 chicks each.

The influence of storage on the supplementary protein nutritive value of certain fish meals, R. J. EVANS, J. S. CARVER, and W. S. HAMM. (Wash. Expt. Sta. et al.). (*Poultry Sci., 23 (1944), No. 6, pp. 491–494*).—As fish meals, demonstrated by Robertson, Carver, and Cook (E. S. R., 84, p. 381) as the most efficient protein concentrate for growing chicks, are largely seasonal and therefore must be stored, study was reported on the effect of wet and dry processes and additions of formaldehyde, sulfuric acid, and oat flour antioxidant on the nutritive value of dogfish meal in relation to storage and meal prepared at different times and commercial pilchard meal. The supplementary nutritive values determined by a modification of the gross value method of Heiman, Carver, and Cook (E. S. R., 82, p. 377) with 15 depleted chicks per lot showed no losses in the supplementary values of 16 fish-meal samples after 10 months' storage, although some had high fat contents. Additions of 0.5 percent formaldehyde and 0.25 percent H_2SO_4 had no effect on the nutritive value of wet-process meal. Dry-process dogfish meal had a lower nutritive value than wet-process meal. Results were not affected by storage in cotton, paper, or burlap bags.

Plant protein concentrates in the chick ration, C. I. DRAPER and R. J. EVANS. (Wash. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 507–509*).—Plant protein concentrates, including soybean meal, Alaska pea meal, and cottonseed meal and combinations of them, were fed to 1,100 day-old Single-Comb White Leghorn chicks in lots of 15 after depletion for 14 days by methods of Heiman, Carver, and Cook (E. S. R., 82, p. 377). Soybean meal had a higher gross value than cottonseed meal or any combination of soybean meal and cottonseed meal. Solvent-process soybean meal had a higher nutritive value than expeller-process meal. The gross value of soybean meal and ground feathers was below that of soybean meal alone.

Dried cow manure and dried rumen contents as a partial substitute for alfalfa leaf meal, J. C. HAMMOND. (U. S. D. A.). (*Poultry Sci., 23 (1944), No. 6, pp. 471–476*).—In a series of 3 experiments, 1,680 Rhode Island Red chicks were distributed in 48 pens for study of weights at 6–10 weeks of age on a basal ration of ground soybean meal, B-Y feed, and alfalfa leaf meal, or substitutes for the alfalfa which included cow manure dried at different temperatures from 21° to 160° C., rumen contents dried at 47°, or several mixtures of feedstuffs. Results were not particularly satisfactory except when cow manure or dried rumen contents were employed with supplements of vitamin A and riboflavin. The very slow drying of cow manure at 21° or by drying at 80° or above decreased the content of riboflavin and the androgenic effects. Sardine meal supported growth on a wartime ration practically as well and feed utilization was as good as when cow manure or dried rumen contents were used as substitutes for alfalfa leaf meal. However, sardine meal did not supplement cow manure. At 6 weeks of age the chicks weighed nearly 400 gm. with dried cow manure as the single supplement, alfalfa meal and fish meal, and dried cow manure and fish meal, but less than 300 gm. with sardine meal as the single supplement.

Corn-and-cob meal for growth of pullets and egg production, D. C. KENNARD and V. D. CHAMBERLIN (*Ohio Sta. Bimo. Bul. 231 (1944), pp. 268–269*).—A preliminary report.

Relation of vitamin D to keel bone deformity in young chickens, S. R. JOHNSON and R. M. SMITH. (Ark. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 510–515*).—Data on the vitamin D necessary for normal keel bone development in chicks from 3 to 5 weeks of age on rations low in vitamin D showed that this vitamin had a uniform and highly significant effect on bone ash. The extent of crookedness of the keels was fairly closely related to bone ash deposition in individual trials. In other trials the crookedness was not serious regardless of the intake of vitamin D. In all trials the extent of crookedness of keels was significantly reduced by adding vitamin D to the ration. The studies were conducted in 7 trials for about 30 days each, with groups of 12–88 chicks in lots receiving 0, 25, 50, 100, and 150 or intervening units of vitamin D from 2 fish-liver oils or Delsterol were added per 100 gm. of the feed. The weights, mean percentage of tibia ash, and keel scores by methods of Hammond et al. (E. S. R., 87, p. 262) were ascertained. Supplementation of a ration extremely low in vitamin D reduced the extent of keel bone deformity, but the exact amount of vitamin D necessary to prevent the deformity was not ascertained because of the influence of other factors such as the genetic make-up, environment, growth rate, mineral content of the rations, and other influencing organic factors which may play a part in keel bone deformity.

Studies on the role of vitamin E in chick nutrition, H. PATRICK and C. L. MORGAN. (S. C. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6. pp. 525–528*).—In further study of the vitamin A and vitamin E relationship (E. S. R., 90, p. 386), it was shown that vitamin E was essential for utilization of vitamin A and carotene in a simplified ration, mostly of dextrin and casein with lard, gelatin, cellophane, and minerals. The weights of the chicks at 4 weeks of age and vitamin A contents of the livers showed that when the rations were supplemented with vitamin A or carotene, with or without α-tocopherol and exposed to indirect sunlight at room temperature for 12 days, there was only a small gain in weight and a trace of vitamin A in the liver. The gains in weight and amounts of vitamin A stored were increased when soybean phosphatide was added to the ration. When α-tocopherol and vitamin A were fed with freshly mixed rations, the weights of the chicks were improved and the vitamin A content of the livers showed a little improvement, but there was considerable improvement, at least in the vitamin A stored, when soybean phosphatides were included. After 6 months' storage (in paper bags) of the commercial ration supplemented with vitamin A and carotene, considerable vitamin A deficiency was noted. Encephalomalacia was frequent when the rations were stored, but when supplied with 100 or 500 International Units of vitamin A or 200 or 500 µg. of carotene per 100 gm. of the ration before feeding, no deficiency was apparent. The vitamin A and carotene appeared to be destroyed more by surface oxidation than by rancidity. Day-old unsexed White Leghorn chicks were used throughout the study.

Is the type of wheat fed a factor in "new wheat disease"? J. B. O'NEIL and W. J. RAE (*Poultry Sci., 23 (1944), No. 6, pp. 548–549*).—Marquis, Apex and Reward varieties of hard red spring wheat did not produce the pullet disease described by Quigley (E. S. R., 92, p. 255). Three groups of 25 Barred Plymouth Rock cockerels were fed for 28 days on rations which included 50–55 percent wheat, some of which was newly threshed. The gains were, however, considerably less where the ration consisted only of whole wheat from a new wheat crop.

Germination differences of wheat utilized in a study of pullet disease, G. D. QUIGLEY. (Md. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 547–548*).—In study of the relation of pullet disease to germination of wheat, the negative groups, so far as disease was concerned, showed high germination, averaging 89.4 percent, whereas those that were positive averaged 68.3 percent germination.

A chronic congenital ataxia in chicks due to manganese deficiency in the maternal diet, C. D. CASKEY, L. C. NORRIS, and G. F. HEUSER. (Cornell Univ.). (*Poultry Sci., 23 (1944), No. 6, pp. 516–520, illus. 4*).—A tetanic spasm of the opisthotonic type, but occasionally spasms of the emprosthotonic or pleurothotonic types, occurred in chickens hatched from hens on a manganese-deficient ration. Histological examination of the brains of the ataxic chicks revealed no evidence of injury. As the chicks became older the ataxia was less evident. Progeny of ataxic parents were not ataxic and developed normally during the first 8 weeks after hatching, indicating the lack of hereditary effects on the condition. Ataxia was observed almost entirely in chicks hatched from eggs of hens receiving a balanced ration containing 6.3 µg. of manganese per gram. With the exception of one chick, no hens on rations with 35 µg. of manganese per gram which had normal hatchability produced chicks with ataxia.

A device for testing the breaking strength of shell eggs, D. C. KENNARD (*Ohio Sta. Bimo, Bul. 231 (1944), pp. 270–273, illus. 4*).—This device was designed for testing eggshell shock by rolling the eggs in a carriage down a slide. A suitable calcium supplement seemed necessary in the ration to give a satisfactory shell strength. Hot weather and magnesium limestone tended to weaken the shells.

Comparative quality losses in eggs stored in fibre and wooden cases, W. KOHLMEYER and C. S. SHAFFNER. (Ind. Expt. Sta.). (*U. S. Egg and Poultry Mag., 50 (1944), No. 7, pp. 295–297, 336*).—Data were recorded on weight loss, candling grade, albumen index, and palatability. After 2, 4, and 6 months' storage the eggs in 30 fiber cases of 10 different types were not consistently different from those stored in 6 new standard wooden cases.

The pasteurization of liquid whole egg, P. A. GRECO (*Iowa State Col. Jour. Sci., 19 (1944), No. 1, pp. 13–19*).—The effect of heat between 56° and 68° C. on the denaturation of whole eggs indicated that the rate of denaturation was 250 times more rapid at 68° than at 56°. Over 99 percent of the culture of *Escherichia coli* was destroyed at 56°, 59°, 62.5°, and 66°; this culture at 62.5° required less than 1 min., whereas another culture required 6 min. for an equal amount of destruction. The age of the eggs had a definite effect on the thermal resistance of the bacteria suspended in the melange. Bacteria were more easily destroyed in melange having a pH of 7.4–7.6 than with a pH of 6.4–6.8, probably accounting for the differences in fresh and aged eggs. *E. coli* was more easily destroyed in egg melange than in milk. The time necessary for destruction of 99 percent of the cells was 7 min. in egg melange and 17.5 min. in milk, largely due to differences in pH. In flash pasteurization studies, egg melange could be effectively pasteurized by heating for 32.5 sec. at 67°. The few surviving organisms were of types commonly found in milk. Probably other types of milk pasteurization equipment could be utilized if there were sufficiently sensitive controls of temperature.

A study of the body type and market finish of the Broad-Breasted Small-type White turkey, M. I. DARROW and C. L. MORGAN. (S. C. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 6, pp. 467–470*).—Study was made of the size, body conformation, and market finish of 851 live Small-type White turkeys at 24 weeks of age, grown under both range and confinement conditions. Weights were recorded and market quality was ascertained in four grades based on fat covering and degree of feathering for males and females. Measurements were compared for those of 6 standard varieties of turkeys reported by R. G. Jaap, T. T. Milby, and R. B. Thompson.[1] The shank length of this variety averaged 0.2 to 0.9 in. shorter for males and 0.3 in. shorter for females than other varieties. The Small-type White turkey has sufficient fleshing at 24 weeks of age, but is lacking in feathering quality.

Lack of water a cause of loose, slimy gizzard linings accompanying early mortality in poults, J. C. HAMMOND. (U. S. D. A.). (*Poultry Sci., 23 (1944), No. 6, pp. 477–480*).—It was concluded, from the results of one experiment with 4 lots of 20 turkey poults each, that lack of water was a primary cause of this condition when associated with early nonspecific mortality. One lot received no feed or water. Other lots had water but no feed, feed but no water, or water and feed. Autopsies of these birds were made at 1 week of age. In another experiment there were 4 lots of 25 poults each, of which one lot received supplements of corn oil with vitamins A and D and 3 other lots received fortified cod-liver oil at 0.5- and 3-percent levels (with corn oil included in one of them). In another experiment 4 lots of 25 poults were given no feed for 24, 48, 72, and 96 hr. after hatching. The turkeys from which feed was withheld 72 hr. showed little interest in eating, but they were force-fed. Gizzard erosion was ascertained at autopsies after 2 weeks.

DAIRY FARMING—DAIRYING

Milk goats in Tennessee, S. A. Hinton and J. J. Bird (*Tennessee Sta. Bul. 193 (1944), pp. 13, illus. 9*).—A general account of the principles of milk-goat production, including diseases found in the State, with descriptions of the breeds and cost of production data.

The milk goat in Canada, J. A. Telfer (*Canada Dept. Agr. Farmers' Bul. 125 (1944), pp. 18, illus. 10*).—General directions for milk goat production, with descriptions of the Toggenburg, Saanen, and Anglo-Nubian breeds.

Physiological factors in lactation relating to milking and mastitis, W. E. Petersen. (Univ. Minn.). (*Cornell Vet., 34 (1944), No. 1, pp. 38–51*).—A general discussion of the development of the mammary gland, lactation, and suggestions for proper milking and the use of the milking machine.

Mastitis and the plate count of milk, III, IV, H. W. Seeley, Jr., E. O. Anderson, and W. N. Plastridge. ([Conn.] Storrs Expt. Sta.). (*Jour. Milk Technol., 7 (1944), No. 4, pp. 191–199*).—These two studies continue this series (E. S. R., 87, p. 847):

III. *A quantitative study of the growth of Streptococcus uberis in various plating media* (pp. 191–194).—Data are reported on the plating in parallel in standard agar, ox-blood agar, and Edwards' crystal violet esculin ox-blood agar. Standard agar and Edwards' medium supported growth of *S. uberis* equally well, but the blood agar supported the growth of about 18 percent more organisms. Colonies grown in standard medium averaged about 37 percent more surface growth than those grown in blood medium. Although blood agar yielded greater numbers of colonies, it did not permit differentiation of *S. uberis* colonies from those of other bacteria found in the mixed flora of milk. Edwards' agar was equal to standard agar in the support of growth of *S. uberis* and permits preliminary identification.

IV. *The contribution of Streptococcus uberis mastitis to the plate count of herd milk* (pp. 195–199).—Partially differential plate counts of samples of milk from 23 udder quarters harboring *S. uberis* showed a geometric mean of 3,000 per cubic centimeter. In this experiment the *S. uberis* counts were not great enough to influence the plate count of high-count milk, but in smaller herds infected animals might materially increase the plate count.

Salt migration in Cheddar cheese curd and its effect on moisture content, pH, and bacterial content, W. H. Hoecker and B. W. Hammer. (Iowa Expt. Sta.). (*Food Res., 9 (1944), No. 4, pp. 278–288, illus. 2*).—Moisture and salt determinations were made on micro-samples from the surfaces and centers of pieces of curd at intervals during the first 72 hr. after hooping. Variations in the bacterial action and pH of the surfaces and centers of the pieces were also ascertained. The cheese was made from pasteurized milk. Approximately 2.5 percent granular salt was added to the milled curd at three intervals of about 15 min. each. The curd was rinsed about 1 hr. after the first addition of salt and placed in hoops and pressed for 48 hr., after which the cheeses were removed and held at 50° F. The moisture contents varied from 39.2 to 40.6 percent, and the salt content from 1.97 to 2.04 percent in 10 samples analyzed by micro-procedures. The moisture contents decreased rather rapidly at both the surface and centers during the first 15 hr. of pressing, with the greatest loss occurring at the surface during the first 5 hr. Salt content at the surface of pieces of curd was relatively high at hooping, but at the centers salt content was low. During pressing there were rapid decreases in the salt content at the surface. There were usually small differences in the salt content of centers and surfaces. Although differences in the pH of the centers and surfaces of curd samples fluctuated somewhat, differences were small 24 hr. after removal from the press. The salt and moisture distribution were fairly uniform after 4 months' ripening. Although bacterial counts were variable, the numbers of bacteria at the centers and surfaces were essentially the same.

Powdered whole milk and milk products—their possible effect upon the future of the dairy industry, P. H. TRACY. (Univ. Ill.). (*Jour. Milk Technol., 7 (1944), No. 4, pp. 206–210*).

VETERINARY MEDICINE

[Contributions on veterinary medicine] (*U. S. Livestock Sanit. Assoc. Rpt., 47 (1943), pp. 31–41, 47–76, 79–92, 94–97, 104–105, 122–183, 186–200, 202–233, 239–253, illus. 5*).—Among the contributions presented at the annual meeting held December 2–4, 1943 (E. S. R., 89, p. 724), are the following: Cooperative Bovine Brucellosis Work in the United States, by A. E. Wight (pp. 31–34) (U. S. D. A.); Thoughts on the Control of Brucellosis in Cattle, by R. R. Birch (pp. 35–41) (Cornell Univ.); History and Result of Calfhood Vaccination in the Dunloggin Herd, by M. M. Rabstein (pp. 47–51) (U. S. D. A.); Brucellosis in Swine, by L. M. Hutchings (pp. 52–58) (Ind. Expt. Sta. coop. U. S. D. A); Twelve Years of Vesicular Exanthema, by C. U. Duckworth and B. B. White (pp. 79–84); Vesicular Stomatitis in Swine, by H. W. Schoening (pp. 85–86) (U. S. D. A.); Pig Mortality, by H. C. H. Kernkamp (pp. 87–89) (Minn. Sta.); Army Inspection of Meat and Milk, by J. E. Noonan (pp. 94–97); Progress and Value of Federal Poultry Inspection in Wartime, by H. A. Weckler (pp. 104–105); A Review of the Literature on Newcastle Disease, by F. R. Beaudette (pp. 122–177) (N. J. Stas.), which includes 77 titles; A Method of Testing Coccidiosis Remedies for Poultry, by G. C. Roe and J. H. Collins (pp. 178–183); The Present Status of Canine Rabies Vaccination, by H. N. Johnson (pp. 190–195); Panel Discussion on Diseases of Cattle (pp. 202–233); The Importance of Continuing Activities in Tuberculosis Eradication in Livestock, by A. E. Wight (pp. 239–241) (U. S. D. A.); Progress in the Eradication of Tuberculosis in Poultry and Swine, by H. R. Smith (pp. 242–247); and The Eradication of Bovine Tuberculosis and Its Effect on the Human Tuberculosis Control Program in Michigan, by G. A. Sherman (pp. 248–251).

Committee reports, among them those on brucellosis, by C. R. Donham et al. (pp. 59–63); parasitic diseases, by J. E. Ackert et al. (pp. 64–73); miscellaneous transmissible diseases, by A. Eichhorn et al. (pp. 74–76); transmissible diseases of swine, by F. L. Carr et al. (pp. 90–92); poultry, by H. J. Stafseth et al. (pp. 186–189); rabies, by H. W. Schoening et al. (pp. 196–200); and tuberculosis, by E. T. Faulder (pp. 252–253).

[Miscellaneous contributions on veterinary research] (*Vet. Med., 39 (1944), No. 12, pp. 451–455, 461–462, illus. 6*).—Articles noted in this issue include the following: Veterinary Reports on the Use of Sulfanilamide Against Anthrax in Cattle and Horses, by R. B. Wilcox (pp. 451–452); Lead Arsenate an Effective Taeniacide for Domestic Ruminants, by R. D. Radeleff (pp. 453–454); Comparison of the Agglutinability of Several *Brucella* Antigens (Rapid Test), by G. R. Bennett (p. 455) (Mich. Expt. Sta.); The Use of Sulfapyridine in the Treatment of Chronic Necrotic Rhinitis ("Bull-Nose"), by E. Adams (p. 461); and Nuttall Death Camas Poisoning in Horses, by M. D. Morris (p. 462).

[Observations on animal diseases] (*Vet. Jour., 100 (1944), No. 9, pp. 176–187, 187–191*).—These articles include Observations on Equine Colic, by J. W. Rainey (pp. 176–182); A Study of 97 Consecutive Cases of Bovine Dystocia as They Were Encountered in the Course of General Practice, II,[1] by J. B. Tutt (pp.

---

182–187); and Pasteurellosis in Poultry and Wild Birds in Tanganyika Territory, by F. G. Waddington (pp. 187–191).

[Contributions on veterinary medicine] (*Jour. So. African Vet. Med. Assoc., 15 (1944), No. 1, pp. 1–16, illus. 4*).—This number includes the following: Biliary Fever of Dogs in East Griqualand, by C. W. A. Belonje (pp. 1–3); Sarcosporidiosis in Sheep, and Its Relation to Certain Forms of Myositis, by A. D. Thomas (pp. 4–5); Eosinophilia in a Dog (Case Report), by B. S. Parkin (pp. 6–7); Foreign Bodies in the Reticulum of a Cow (Case Report), by V. R. Kaschula (pp. 8–9); Psittacosis in a Budgerigar (*Melopsittacus undulatus*), by J. D. W. A. Coles (pp. 10–12); A Simple Method of Obtaining Large Amounts of Sterile Blood From Fowls, by D. A. Haig and J. D. W. A. Coles (pp. 13–15); and Giemsa Staining of Large Numbers of Smears, by M. C. Lambrechts (p. 16).

Diagnostic methods in veterinary medicine, G. F. Boddie (*Edinburgh: Oliver & Boyd, 1944, pp. 328+, illus. 31*).—The object of this work is to present a description of the diagnostic methods used in veterinary medicine and details of their interpretation. A chapter on clinical hematology, by H. H. Holman, is included.

Some clinical diagnostic methods of use in conditions associated with animal parasites, M. L. Bingham (*Vet. Rec., 56 (1944), No. 35, pp. 313–316*).—This describes mainly technics used at the Research Institute in Animal Pathology at Streatley, Berks, England.

Vitamins of the B complex in surgical practice, J. L. Davidson (*Vet. Med., 40 (1945), No. 1, pp. 16–18, illus. 1*).—The author feels that the use of vitamins of the B complex in surgical practice in veterinary medicine is of great importance and will in certain cases decide the difference between recovery and death. "This therapy is especially indicated in all forms of septic surgery and in those cases which require a preparatory glucose infusion. In those cases in which bleeding may be extensive or prolonged, it is felt, in view of work which has been done, that the parenteral administration of thiamine hydrochloride in therapeutic doses is definitely indicated."

Studies on the vitamin requirement of tapeworms, C. J. Addis and A. C. Chandler (*Jour. Parasitol., 30 (1944), No. 4, pp. 229–236*).—To test the effects of the presence or absence of various vitamins and vitamin combinations on the establishment and growth of *Hymenolepis diminuta,* groups of six female albino rats were infected with 10 cysticercoids each and autopsies made on the fourteenth day. The average number of worms per rat was reduced by a diet deficient in either the fat-soluble vitamins or the G complex and was reduced still further when both of these vitamins were missing. It is suggested that the effect of the lack of the fat-soluble vitamins may be due to some disturbance in the secretion of bile, thus preventing the proper evagination of the cysts. The absence of vitamin B_1 had very little, if any, effect upon the establishment of the worms.

The experiments corroborated previous evidence that the lack of some factor associated with the G complex in the diet of the host causes a marked stunting in the growth of the worms. This becomes more marked the longer the depletion period of the host prior to infection, suggesting that the necessary component is absorbed from the host's mucous membrane and is not obtained in adequate amount in a depleted host. The lack of vitamins A, D, and E or B_1 in the diet of the host causes an increase in size of the worms present. It is suggested that "this increase in size over that of the controls is the result of the partial paralysis of the intestine, brought about by the vitamin deficiency, thus enabling the worms to become established in a more favorable anterior position. Since the worms grow in a perfectly normal manner in the absence of any vitamin in the diet of the host except something associated with the G complex, even after a long depletion period which should reduce them in the tissues with which the worms are in contact, the possibility of synthesis of these vitamins by the worm is suggested."

Propamidine in wound sepsis, A. R. WITHERS and G. S. POWLEY (*Vet. Rec., 56 (1944), No. 34, p. 308*).—Successful results obtained with both large and small animals with an aromatic diamidine preparation are noted.

The chemoprophylactic and therapeutic action of a wide variety of chemical compounds on two neurotropic virus infections in mice, S. D. KRAMER, H. A. GEER, and D. A. SZOBEL (*Jour. Immunol., 49 (1944), No. 5, pp. 273–314*).—This report gives the results of 412 experiments testing the prophylactic and therapeutic value of 190 chemical compounds on poliomyelitis and St. Louis encephalitis infections in white Swiss mice. A list of 71 references is appended.

The combined bacteriostatic activity of sulfanilamide and azochloramid upon streptococci in in vitro and in vivo studies, F. M. SKELTON. (S. Dak. Expt. Sta.). (*Jour. Bact., 47 (1944), No. 3, pp. 273–275*).—The bacteriostatic activity of azochloramide and of sulfanilamide toward *Streptococcus agalactiae* (group B) was found to be greater when the two drugs are used in combination than when either is used alone in like or higher concentrations. However, the combined use of azochloramide and sulfanilamide in the treatment of infectious bovine mastitis appeared to give unsatisfactory results.

A powerful inhibitory substance produced by group N streptococci, A. T. R. MATTICK and A. HIRSCH (*Nature [London], 154 (1944), No. 3913, p. 551*).—Tests of an inhibitory substance produced by a streptococcus isolated from stored milk by Whitehead (E. S. R., 71, p. 151) revealed marked inhibitory properties in vitro toward many groups of pathogenic streptococci, some species of *Bacillus, Clostridium,* and lactobacilli. Concentration of this substance resulted in a product of high potency which completely inhibited the growth of *Streptococcus agalactiae* in a dilution of 1 : 640,000 and had marked therapeutic properties when given intravenously to a mouse following inoculation with a mouse-virulent hemolytic streptococcus. Additional tests with 20 control mice and 20 mice receiving about 10,000 lethal doses of the streptococcus also showed marked therapeutic results. Experiments in purification and application are being continued.

Preliminary clinical report on vivicillin, E. VON LUSTIG-LENDVA (*Vet. Rec., 56 (1944), No. 22, pp. 178–179*).—This is a preliminary report on the results achieved in clinical tests, mainly in small animals, with a standardized antibacterial pyrogen-free metabolite preparation containing living *Penicillium notatum* Fleming.

Studies on the toxicity of gold compounds in rats, C. W. DENKO and A. K. ANDERSON. (Pa. Expt. Sta.). (*Jour. Lab. and Clin. Med., 29 (1944), No. 11, pp. 1168–1176*).—The nonprotein nitrogen value of the blood has been used in determining the toxicities of several commercial and experimentally synthesized gold compounds. High blood nonprotein values were always found where tissue changes indicating kidney damage had occurred. In some cases high blood nonprotein nitrogen values occurred where there was no evidence of tissue change.

The respiration of the protozoan parasite, Eimeria tenella, B. F. SMITH and C. A. HERRICK. (Wis. Expt. Sta.). (*Jour. Parasitol., 30 (1944), No. 5, pp. 295–302*).—Studies on the metabolic rate of *E. tenella* and invaded tissues were carried on. Oocysts and tissues were supplied by Leghorn chickens weighing approximately 700 gm. if used for oocyst production or 300 gm. if used in studies of the respiration of the coccidia within the epithelial cells of the cecal pouches.

The oxygen consumption of tissue parasitized with *E. tenella* was significantly higher than that of normal tissue. The respiration of unsporulated oocysts was from 10 to 20 times greater than that of sporulated oocysts. The respiration of oocysts remained fairly constant within the pH range of 1.2 to 8.8.

Investigations on rickettsial diseases in Texas, III, IV (*Tex. Rpts. Biol. and Med., 1 (1943), No. 4, pp. 371–388, illus. 9; pp. 389–409, illus. 9*).

III. *Spotted fever: Protection of laboratory animals by intradermal inoculation of immune rabbit serum,* L. Anigstein, M. N. Bader, G. Young, and D. Neubauer.—From these studies with guinea pigs of the intradermal route for separate inoculation of spotted fever virus and immune serum, it is concluded that "due to a certain biological autonomy of the skin as an organ, it is possible to create a local immunity by introduction of a pathogenic agent (bacterial or viral), which phase is eventually followed by a general and solid immunity. In the present studies an interception of the virus has been attained in various degrees at the site of the original injection by employing varying minute amounts of specific serum."

IV. *Experimental study of Bullis fever,* L. Anigstein and M. N. Bader.—An infectious agent, not cultivable on ordinary bacteriological media, has been recovered from guinea pigs inoculated with ticks (*Amblyomma americanum*) collected from the military reservation area at Camp Bullis, Tex. The place of origin of the ticks has been for the last 2 yr. the scene of mass outbreaks of an apparently new clinical syndrome, called Bullis fever. The results of the present work demonstrate that *A. americanum* is the vector or at least one of the carriers of Bullis fever in nature.

Salmonella loma-linda: A new type isolated from meningitis, P. R. Edwards. (Ky. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc., 57 (1944), No. 1, pp. 104–106*).—A new *Salmonella* type, *S. loma-linda,* is described, represented by the antigenic formula IX, XII:*a-e, n, x* . . .

Host list of the genus Trichomonas (Protozoa: Flagellata).—II, Host-parasite list, B. B. Morgan. (Wis. Expt. Sta.). (*Wis. Acad. Sci., Arts, and Letters, Trans., 35 (1943), pp. 235–245*).—Supplementing part 1 (E. S. R., 89, p. 706), the species are given after the names of their respective hosts, these being listed by phyla, classes, orders, and families.

The adaptation of Mycobacterium paratuberculosis to artificial culture media prepared without the addition of the "essential substance," H. Konst (*Canad. Jour. Pub. Health, 35 (1944), No. 10, pp. 392–395*).—Although *M. paratuberculosis,* the causative agent of chronic paratuberculosis enteritis of cattle and sheep, is commonly distinguished from the tubercle bacillus in part by the fact that its isolation from the natural host has been considered possible only on culture media to which a growth factor has been added, seven freshly isolated strains were adapted to Long's synthetic medium prepared without the addition of the supposedly essential substance. This fact suggests that *M. paratuberculosis* may be adapted in a comparatively short time after its isolation from the natural host to suitable plain artificial media. Although some variability may occur in occasional strains due to the prolonged cultivation on such media, most strains retain their original gross cultural characteristics and are suitable for the production of a potent diagnostic agent.

Trials to increase the luxuriance of adapted strains of *M. paratuberculosis* by cultivation on Dorset's synthetic medium (E. S. R., 71, p. 98) at various pH levels were unsuccessful.

Development and survival under outdoor conditions of eggs and larvae of the common ruminant stomach worm, Haemonchus contortus, A. G. Dinaburg. (U. S. D. A.). (*Jour. Agr. Res. [U. S.], 69 (1944), No. 11, pp. 421–433*).—This is a quantitative study of the rates of development and survival of the various free-living stages of *H. contortus* under the influence of natural weather conditions at Beltsville, Md., from August 1939 to October 1940.

When eggs of *H. contortus* were exposed outdoors for 3 days or more to mean maximum temperatures below 65° F., few preinfective larvae—those recovered after 3 or 6 days' exposure— and no infective larvae—those recovered after 13 or more days—were found during the experiments, regardless of the amount of rainfall. With mean maximum temperatures between 66° and 84° during the first 3 days, the amount of rainfall in the week preceding and the 3 days following exposure of the eggs considerably affected the degree of their development. After 13 to 20 days outdoors, with no rainfall, infective larvae recovered, based on the number of controls, at no time exceeded an average of 0.01 percent; with 0.12 to 0.72 in. and 0.88 to 2.09 in. of rainfall, the highest averages were 0.5 and 21 percent, respectively. Higher percentages of preinfective larvae were recovered. With mean maximum temperatures between 86° and 93° and 0.26 to 1.57 in. of rainfall, the highest recovery of infective larvae was 8 percent, after 13 days. Exposure to full sunlight resulted in lower yields of larvae than exposure to full shade or partial shade. In the middle temperature range, recoveries from exposure to full and partial shade were about the same. In the upper temperature range recoveries from the former were consistently higher than from the latter.

It is concluded that "eggs do not survive exposure to mean maximum temperatures below 70° for more than 6 to 13 days, as shown by cultures, or for more than 13 to 20 days, as shown by salt flotations. Above 70°, salt flotations indicate that eggs do not survive more than 6 to 13 days outdoors.

"In designating large periods of the year as unfavorable for the survival and development of the eggs of *H. contortus,* temperature is a more reliable weather factor than rainfall."

Bionomics of the lymnaeid snail, Stagnicola bulimoides techella, the intermediate host of the liver fluke in southern Texas, O. W. OLSEN. (U. S. D. A.). (*Jour. Agr. Res.* [*U. S.*], *69* (*1944*), *No. 10, pp. 389–403, illus. 4*).—Information on the bionomics of this snail was sought because of the importance of the liver fluke (*Fasciola hepatica* Linn.) as a parasite of cattle and sheep in the Gulf coast region of the United States. Slaughter records for 10 yr. under Federal meat inspection, obtained from six Gulf coast packing houses in Texas, Louisiana, and Florida, showed 37.5 percent of the native adult cattle and 6 percent of the calves to be infected with the liver fluke. Field investigations were made in 1940 and 1941 in the Gulf coast prairie region of Texas, and laboratory studies were carried on simultaneously.

The study showed that the snails live in the temporary and semipermanent pools that are scattered over the entire area. The pools are generally only slightly alkaline in reaction and have extensive soil-water peripheries where the snails live. The life cycle of *S. bulimoides techella* follows a rather well-defined pattern with two generations annually. One generation occurs in midwinter and the other late in the spring. When the habitats become dry in the spring or early in the summer, the young snails estivate in the soil until the fall rains. Development of the snails is rapid under favorable conditions, being as short as 20 days from egg to egg. The adult snails usually die when about 6 mo. old, after the period of reproduction. Under laboratory conditions, the snails were found to remain alive as long as 25.5 mo., during which time standing water was present in the aquarium for 2 to 7 days only at the beginning of each month. The snails are capable of withstanding periods of desiccation as long as 5 mo. under field conditions when estivating in the soil or when exposed in an open dish in the laboratory. The lethal effect of drought on the snails when the pools become dry is immediate rather than cumulative.

Egg production of individual snails is high. They have been found to produce as many as 6,479 eggs during a life span of 5 mo. and a laying period of 129 days. The snails surviving the summer drought are predominantly juveniles; they emerge from estivation when the fall rains restore the pools, develop rapidly, and oviposit. The snails do not migrate, but they may be distributed widely by water during periods of heavy rainfall when the country is inundated. The mean infection with liver fluke of 16,276 snails dissected during 1 yr. was 0.0051 percent. In one temporary pool the rate of infection in the latter part of November was 6.6 percent. Natural infection was found to occur throughout the year.

Brucellosis: An outline of the disease in man and animals, W. S. STONE (*N. Y. State Vet. Col. Rpt., 1942–43, pp. 95–107, illus. 4*).

The effect of Brucella abortus strain 19 on cattle of various ages and its bearing on adult cattle vaccination, C. M. HARING and J. TRAUM. (Univ. Calif.). (*U. S. Livestock Sanit. Assoc. Rpt., 47 (1943), pp. 42–46, illus. 1*).—Observations on the incidence of brucellosis as influenced by the use of strain 19 in cattle of various ages under controlled experimental conditions as well as in commercial dairy herds are reported. The resistance produced by the vaccination was apparently greater in animals adolescent or mature at vaccination than in calves vaccinated when younger than 9 mo. After the infection had become established, there was very little difference between the calf crop of the group vaccinated as adults and that vaccinated as calves. Abortion in rare instances followed the injection of strain 19 with pregnant cows after the fourth month of lactation, and some loss of milk production has resulted in lactating cows. Nevertheless, it is concluded that strain 19 "is the only product at present that has been used on thousands of animals with any degree of satisfaction."

Adult vaccination against brucellosis in cattle, W. V. LAMBERT ET AL. (*Jour. Amer. Vet. Med. Assoc., 105 (1944), No. 811, pp. 190–193*).—This report, published with the approval of the committee on animal health of the National Research Council, points out that the ultimate goal of the livestock industry should be the elimination of brucellosis from the animal population, and indicates that "the intelligent use of strain 19 vaccine should contribute materially to this end." Recommendations for procedure are offered, and the need for additional research is emphasized.

Clinical aspects of "grass staggers"—milk fever syndrome, A. A. BLAKELY (*Vet. Rec., 56 (1944), No. 22, pp. 175–176*).—Three classes of this disease of cattle in New Zealand are described, (1) identified with grass tetany, (2) a complicated "milk fever," and (3) an acetonemia of nervous type, superimposed upon a low blood Mg level.

Bovine leptospirosis, E. JUNGHERR. ([Conn.] Storrs Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc., 105 (1944), No. 812, pp. 276–281, illus. 8*).—The present report deals with the pathologic investigation of three fatal "mysterious" deaths in adult cows in Connecticut during 1943–44. In one of them, illness developed at the height of milk production, and was characterized by anorexia, subnormal temperature, and terminal convulsion on the sixth day. The only gross lesion was so-called nutmeg appearance of the liver which corresponded microscopically to multiple areas of sinusoidal congestion and hemorrhage associated with extensive parenchymatous necrobiosis. Levaditi preparations showed numerous *Leptospira*-like bodies in the liver and few in the kidneys. The spleen showed extensive hemosiderosis.

Two cows died on another farm in 1 week, the loss occurring within 2 days after normal calving. Symptoms consisted of milk preparturient fever, anorexia, and bloody milk. Gross pathology was characterized by edema and hemorrhage in the udder, numerous petechiae and ecchymoses in the subcutis and subserosae, and abnormal striation of the renal cut surface. Microscopically, one case showed large foci of tubular karyolytic necrosis in the kidneys, associated with large nests of *Leptospira* organisms in silver impregnated sections. The other case showed, primarily, foci of tubular hypertrophy in the kidneys and nests of *Leptospira* in an adjacent mesenteric lymph node.

records showed that the single determination would have led to a correct interpretation in 95 percent of the cases.

Vitamin synthesis by torula yeast, J. C. LEWIS, J. J. STUBBS, and W. M. NOBLE. (U. S. D. A.). (*Arch. Biochem., 4 (1944), No. 3, pp. 389–401*).—*Torulopsis utilis* propagated under aeration in a fruit juice medium produced a tenfold yield in terms of the inoculum in a 6–8-hr. period. Vitamin balance experiments in which vitamin assays were made on inocula and fruit juices, as well as the crop yeast and spent liquors, indicated synthesis of the B vitamins by the yeast. Although the amount synthesized varied in the different fermentation runs, the averages in micrograms per gram of dry yeast produced amounted to 22, 71, 530, 241, 1.23, 35, and 56 for thiamine, riboflavin, nicotinic acid, pantothenic acid, biotin, pyridoxin, and *p*–aminobenzoic acid, respectively. In some cases there was appreciable absorption of the vitamins originally present in the medium, while in others there was excretion of the vitamin from the yeast into the medium. Although the vitamin content of the yeast was roughly comparable to that of bakers' and brewers' yeast, the high yields of *T. utilis* obtainable from cheap substrates make it an outstanding vitamin producer.

B vitamins in germinating seeds, V. H. CHELDELIN and R. L. LANE (*Soc. Expt. Biol. and Med. Proc., 54 (1943), No. 1, pp. 53–55*).—Samples of black-eyed peas, lima beans, and cottonseeds were assayed before and after germination for their content of the various B vitamins. The values, reported on the basis of total solids, indicated that germination of the seeds was accompanied by increases in the content of most B vitamins. The increases were greatest for nicotinic acid, followed by pyridoxine, pantothenic acid, riboflavin, inositol, and biotin. Thiamine was a border-line case. Folic acid increased in peas and in one sample of lima beans. Corn and bush lima beans analyzed at different stages of growth were found to reach a peak in B-vitamin values at a relatively early stage of development, after which they decreased in vitamin value as the seeds matured.

Biotin.—Annotated bibliography, 1944 (*Rahway, N. J.: Merck & Co., 1944, rev., pp. 104+*).—In this annotated bibliography, the literature on biotin is summarized under the headings chemical investigation and description, occurrence, physiological activity, clinical uses, method of assay, and reviews.

Utilization of biotin and biotin methyl ester by Lactobacillus casei, J. L. STOKES and M. GUNNESS (*Soc. Expt. Biol. and Med. Proc., 54 (1943), No. 1, pp. 28–31, illus. 1*).—Three different strains of *L. casei* were utilized in tests employing the general procedure and medium of Landy and Dicken (E. S. R., 90, p. 298) in the assay method for biotin. The crystalline biotin or biotin methyl ester in fresh solution was added to the medium which, after sterilization by autoclaving, was inoculated with the organism whose response was followed by estimating the amount of acid formed. Essentially maximum acid formation occurred with two different preparations of the methyl ester of biotin as well as with biotin, indicating that both of these substances could be used by *L. casei*. With the ester, however, growth and fermentation were slower than with free biotin.

Investigations on the food value of fish and other marine products, I, II (*Indian Jour. Med. Res., 30 (1942), No. 2, pp. 315–318; 31 (1943), No. 1, pp. 25–27*).

I. *The antipellagra vitamin (nicotinic acid)*, M. L. Khorana, M. L. Sarma, and K. V. Giri.—Nicotinic acid was determined in the muscle tissue of 17 fish, and in prawns, crabs, and cuttle fish, all obtained from the coastal waters of Waltair; these were economically important foods in the northern Circars, and the specimens are designated for the most part by common English, local, and zoological names. Nicotinic acid was determined in muscle extracts obtained by alkaline hydrolysis of the finely minced tissue. The nicotinic acid in the neutralized extract was adsorbed on medicinal charcoal and eluted with an alcohol-NaOH mixture. The eluate was adjusted to pH 5.6, treated with acetate buffer, and then with the reagents cyanogen bromide and *p*-aminoacetophenone; the color developed was measured colorimetrically against a standard similarly treated. The nicotinic acid content of these fish-muscle tissues ranged from 0.63 to 4.8 mg. per 100 gm. of fresh tissue.

II. *The protein and mineral contents,* M. L. Khorana, M. L. Sarma, P. Seshagiri Rao, and K. V. Giri.—Protein, Ca, P, Fe, and Cu were determined, by methods noted, in the muscle tissue of 12 of the food fishes. The protein content ranged from 18 to 23 percent, Ca from 0.006 to 0.090, and P from 0.150 to 0.356 percent; Fe from 0.6 to 2.5, and Cu from 0.01 to 0.24 mg. percent.

Nicotinic acid in products of commercial rice milling and in rice varieties, M. C. Kik and F. B. Van Landingham. (Ark. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 2, pp. 154–158*).—Data for nicotinic acid as determined by the method of Melnick (E. S. R., 89, p. 11) are reported for samples previously analyzed for thiamine and riboflavin (E. S. R., 91, p. 488). The average nicotinic acid content of paddy or rough rice was 49.2 µg. per gram and of the whole brown rice 55.1 µg. per gram.

"Of the finished, clean products, the end product, head rice (sold for human consumption), contained an average of 18.4 µg. and second head 17.7 µg. per gram of dry matter. An average of 66.4 percent of nicotinic acid was removed during the milling process. Screenings and brewers' rice contained 23.8 and 36.1 µg. nicotinic acid, respectively. Of the byproducts, hulls contained 18.6 µg. per gram, bran from 262.8 to 358.2 µg. per gram, and rice polish 206.6 to 408.0 µg. per gram of nicotinic acid. Three samples of milled parboiled rice (prepared in three different localities) contained 49.0, 45.2, and 45.0 µg. of nicotinic acid per gram of dry material. Two samples of undermilled rice contained 26.2 and 26.6 µg., compared with 19.5 and 18.9 µg. per gram in the milled rice. The average nicotinic acid content of all varieties (rough rice) was 46.5 µg. per gram. The nicotinic acid content of rice differed with variety and to a small extent with locality."

The effect of calcium pantothenate and paraaminobenzoic acid on gray hair in man: A study on a group of young and older individuals, H. Brandaleone, E. Main, and J. M. Steele (*Amer. Jour. Med. Sci., 208 (1944), No. 3, pp. 315–321*).—Confusing reports on the effect of calcium pantothenate and *p*-aminobenzoic acid on gray hairs in man or animals are reviewed. Several series of tests on humans are reported, with the finding that out of 33 gray haired subjects treated with calcium pantothenate and *p*-aminobenzoic acid alone or combined and with and without brewers' yeast only 2 showed significant changes in the color of the hair during the treatment, which consisted in their case of 100 mg. of calcium pantothenate, 200 mg. of *p*-aminobenzoic acid, and 50 gm. of brewers' yeast daily. These 2 subjects were in a group of 19 individuals over 55 yr. of age. In a group of 8 younger individuals, 6 of whom received for 6 mo. the same treatment as noted and 2 the same without the brewers' yeast, and in another group of 6 younger individuals who received 20 mg. of calcium pantothenate and 3.5 gm. of concentrate yeast daily, there was no return of the previous color of the hair. A common occurrence was the appearance of a yellowish or greenish cast to the gray hair, usually appearing during the first few months and not always persisting. Another frequent appearance was new growth of scattered wiry black hairs.

Effect of alanine on response of Lactobacillus casei to pyridoxine and folic acid, E. E. Snell (*Soc. Expt. Biol. and Med. Proc., 55 (1944), No. 1, pp. 36–39*).—The technic previously employed (E. S. R., 88, p. 712) was used with the medium modified to be almost identical with that of Landy and Dicken (E. S. R., 90, p. 298). Various vitamins were omitted in turn from this medium, and the quantitative growth response to additions of the vitamin was determined in the presence and absence of *dl*-alanine at a level of 2 mg./10 cc. The presence of *dl*-alanine improved the response of the organism to each vitamin as present in a concentration limiting growth. The improvement was very slight with riboflavin, however, and only a little more marked with pantothenic acid and nicotinic acid. With pyridoxin and folic acid the response was especially pronounced. On the folic acid-free medium a number of concentrates derived from spinach were found to differ in their relative effectiveness in promoting growth of *L. casei*, depending upon whether *dl*-alanine was present in the medium.

Effect of pseudopyridoxine on rat and yeast growth, L. E. CARPENTER, C. A. ELVEHJEM, and F. M. STRONG. (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc., 54 (1943), No. 1, pp. 123–125*).—Pseudopyridoxine formed from pyridoxine by autoclaving in a cystine solution or by treating with hydrogen peroxide, as well as that formed by autoclaving an acid solution of yeast extract, failed to stimulate rat growth as determined by assaying the above preparations by the method of Conger and Elvehjem (E. S. R., 86, p. 427). The pseudopyridoxine likewise failed to stimulate yeast growth, although it exerted physiological activity toward *Lactobacillus casei.* Pseudopyridoxine in the several preparations was determined, therefore, by the differential assay procedure, involving preliminary estimation of both pyridoxine and pseudopyridoxine with *L. casei* followed by determination of pyridoxine alone by the yeast method of Atkin et al. (E. S. R., 90, p. 9).

Microbiological differentiation of pyridoxine and pseudopyridoxine, B. C. JOHNSON. (Univ. Ill.). (*Soc. Expt. Biol. and Med. Proc., 55 (1944), No. 3, pp. 199–201*).—Human sweat concentrated 2 to 1 was found to contain 0.0018 µg. pyridoxine per cubic centimeter by the procedure of Atkin et al., employing the yeast *Saccharomyces carlsbergensis* (E. S. R., 90, p. 9) and 4 µg. of pyridoxine equivalents of pseudopyridoxine, using the procedure of Carpenter et al. noted above and employing the bacteria *Lactobacillus casei.* The separation of pyridoxine from the pseudopyridoxine in sweat involved elimination of the pyridoxine by yeast growth, filtration of yeast cells, and assay of the filtrate for pseudopyridoxine. In a similar manner pseudopyridoxine was eliminated by bacterial growth, the bacterial cells removed by filtration, and the filtrate assayed for pyridoxine.

Inactivity of coramine (nikethamide) for L[actobacillus] arabinosus and its conversion to an active substance, L. J. TEPLY and C. A. ELVEHJEM. (Univ. Wis.). (*Soc. Expt. Biol. and Med. Proc., 55 (1944), No. 1, pp. 72–73, illus. 1*).—Nikethamide (pyridine β-carboxylic acid diethyl amide) tested on *L. arabinosus* was found to have 0.03 percent of the activity of an equimolar amount of nicotinic acid. Hydrolysis of the compound, by autoclaving it at 15 lb. pressure for 1 hr. with various concentrations of NaOH, HCl, and H_2SO_4, served to convert it to an active compound; NaOH was most effective in bringing about this conversion and H_2SO_4 the least effective. Nikethamide was less rapidly converted to an active compound than the "precursor" found in wheat bran.

Riboflavin content of milk and milk products, L. DANIEL and L. C. NORRIS. (Cornell Univ.). (*Food Res., 5 (1944), No. 4, pp. 312–318*).—The riboflavin content of 18 different dairy products was determined by fluorometric and biological procedures. The fluorometric method was essentially that of Hodson and Norris (E. S. R., 83, p. 151) and involved extraction of the samples by refluxing with an acid-acetone mixture; after filtration and removal of interfering pigments from the filtrate by treatment with $KMnO_4$ and H_2O_2 at pH 3.7, final readings on the filtrate were made photofluorometrically against a similarly treated standard riboflavin solution. The microbiological procedure used was that of Snell and Strong (E. S. R., 82, p. 587) modified to eliminate acid extraction with substitution of acid-acetone extraction or enzymatic digestion; and to remove by filtration any precipitate formed in autoclaving the sample, and by petroleum ether extraction the butterfat in samples containing more than 5 percent fat. Statistical analysis based on individual values showed that there was no significant difference between these fluorometric and microbiological methods when applied to dairy products. It is considered, therefore, that the values obtained represented actual riboflavin content. "The average riboflavin values on the fresh basis of the products studied were as follows: Dried sweet-cream buttermilk, 33.65; dried whey, 20.72; dried skim milk, spray process, 19.81, roller process, 18.81; dried whole milk, spray dried, 15.44, roller dried, 14.76; Cheddar cheese, 4.71; condensed milk, 3.95; evaporated milk, 3.57; cottage cheese, 3.00; cream cheese, 1.87; liquid whole milk, 1.77; liquid skim milk, 1.58; liquid buttermilk (cultured), 1.56; light cream, 1.47; liquid whey, 1.24; and butter, 0.367 µg. per gram."

The antiriboflavin effect of isoriboflavin, G. A. EMERSON and M. TISHLER (*Soc. Expt. Biol. and Med. Proc., 55 (1944), No. 3, pp. 184–185, illus. 2*).—An isomer of riboflavin, 5,6-dimethyl-9-(*d*-1′-ribityl)-isoalloxazine, was found to inhibit the growth-promoting action of riboflavin for rats when this was fed in suboptimal amounts. The antagonistic effect was overcome or prevented by feeding adequate levels of riboflavin.

Thiamin content of peanut butter, T. A. PICKETT (*Georgia Sta. Cir. 146 (1944), pp. 8, illus. 3*).—Sixty samples of commercially prepared peanut butter obtained from 36 large and small manufacturers throughout the country and analyzed for thiamine by the method of Conner and Straub (E. S. R., 87, p. 9) contained from 0.3 to 3.6 µg. thiamine per gram. The average was slightly over 1 µg. per gram. One other sample fortified with thiamine equaled the specifications on the label. Riboflavin, determined by the method of Hodson and Norris (E. S. R., 83, p. 151), in eight of the samples selected at random averaged 1.35 µg. per gram (1.18–1.55 µg.). The dark-colored samples (as indicated by visual inspection and by spectrophotometric measurements of light transmission of methanol extracts of the defatted samples) contained less thiamine than light-colored samples.

Blanched peanuts with skins removed were heated in experimental lots at air temperatures of 140°, 150°, and 160° C. In a total roasting period of 15 min., more or less, a large portion of the thiamine in the peanuts was destroyed, particularly at the higher air temperature. Although a long roast at low temperatures appeared to be preferable in preserving the thiamine content, it was found very difficult, if not impossible, to obtain peanut butter with a large percentage of the original thiamine of the raw nuts without underroasting, and this practice was very detrimental to the flavor, color, and general desirability of the product.

Retention of thiamine in canned vegetables, L. E. CLIFCORN and D. G. HEBERLEIN (*Food Packer, 25 (1944), Nos. 5, pp. 32–33; 6, pp. 54, 56, 58*).—"Surveys on the effect of various steps in the preparation and canning of several vegetables reveal that blanching and processing are of greatest concern in the preservation of thiamine. The retention of thiamine during the commercial blanching of asparagus, green beans, lima beans, and peas (Alaska and sweet varieties) ranges from 64 to 100 percent and during commercial processing from 58 to 79 percent. The over-all thiamine retention for the nine products studied, based on the total contents of the can, ranges from 31 to 89 percent with an average over-all retention of 57 percent. The thiamine content of canned vegetables is significantly affected by grade and size of some of the raw products and by the segment of the stalk canned in the case of asparagus. Experiments indicate a decrease in the thiamine content of canned vegetables upon storage. The liquid portion of canned vegetables contains between 27 and 45 percent of the total thiamine in the can. This amount, together with the other water-soluble nutrients in the liquid, emphasizes the importance of utilizing this portion of the canned product in the diet."

Effect of commercial canning on the thiamine content of vegetables, L. E. CLIFCORN and D. G. HEBERLEIN (*Canner, 98 (1944), No. 17, pp. 12–15, 26*).—Essentially noted above.

Effect of canning on thiamine content of vegetables, L. E. CLIFCORN and D. G. HEBERLEIN (*Food in Canada, 4 (1944), No. 3, p. 31*).—Essentially noted above.

Influence of ingredients on thiamin content of biscuits, V. R. WILLIAMS and E. A. FIEGER. (La. Expt. Sta.). (*Food Res., 9 (1944), No. 4, pp. 328–337*).—This study was carried out to determine (1) the effect of shortening, (2) the influence of different leavening agents, and (3) the variation due to the source of vitamin for enrichment upon the thiamine content of quick breads, such as biscuits. To avoid losses of thiamine due to oven drying of the biscuits preliminary to sampling for analysis, a method was developed involving the use of 75 gm. of cut pieces (⅛ in. thick) of the biscuits and 200 cc. of 0.1 N H_2SO_4 blended for 4 min. in a Waring blender. After dilution to 500 cc., the mixture was poured into a beaker and kept homogeneous by an electric mixer during the removal of 50 cc. aliquots; after further dilution of each aliquot with 20 cc. of 0.1 N H_2SO_4, the samples were ready for hydrolysis and determination of thiamine by the method of Hennessy. Samples prepared by the new method exceeded dried samples by 0.35–16.74 (average 7.72) percent in thiamine content, and 18 to 24 hr. of time were saved in the preparation of samples. To eliminate any discrepancy due to the presence of fat, in the comparison of shortened and unshortened biscuits steapsin was added to samples in the extraction process. The steapsin (0.25 gm. per sample), introduced with the diastase and the sodium acetate buffer, made a marked difference in the character of the extracts, which attained sparkling clarity, filtered rapidly, leaving a small residue, and quickly passed through the base-exchange columns. This effected further time-saving in the analytical procedure and an increase of at least 5 percent in the assay value (after correction for the thiamine content of the steapsin) in both shortened and unshortened biscuits. No significant differences were found in the thiamine content of these two types of biscuits. Biscuits made of enriched flour and those made of enriched flour, three parts, and rice polish, one part, showed no difference in thiamine retention, about 82 percent of the thiamine value of the dry ingredients being retained in the baking process. The source of the thiamine apparently had no influence on the degree of retention. Biscuits made with the addition of rice polish averaged 8.09γ thiamine per gram dry weight as compared with 3.62γ per gram in those made from the enriched flour alone. Biscuits made with soda and lactic acid as the leavening agent (simulating sour-milk biscuits), with cream of tartar baking powder, with calcium acid phosphate baking powder, and with sodium aluminum sulfate-calcium acid phosphate baking powder showed, in that order, a decreasing thiamine content, which was associated with increasing pH of the dough mixtures.

Availability of vitamins in foods and food products.—I, Utilization of thiamin in brewers' yeasts, B. SURE. (Ark. Expt. Sta.). (*Arch. Biochem., 4 (1944), No. 3, pp. 413–418*).—In this study, the results of which are presented in a summarized form, the author, with the technical assistance of L. Easterling, conducted thiamine balance tests according to methods developed by Sure and Ford (E. S. R., 89, p. 504) on 3 sets of 24 rats each, using 3 brands of brewers' yeast with thiamine values of 440γ, 670γ, and 160γ per gram, respectively. In the first series, male and female rats 46 days old at the beginning of the experiment were used; in the second, male rats 65 days old; and in the third, male rats 34–43 days old. The first series was arranged to compare the efficiency of utilization of the thiamine of the yeast by males and females, the second to compare the utilization of the thiamine in the brewers' yeast with pure crystalline thiamine, and the third to study the influence of body weight on the efficiency of thiamine utilization in the yeast.

All series showed excellent utilization of the thiamine in the yeast, ranging from 93 to 100 percent. In the first series, the males given 50 and 150 mg. of the yeast daily showed 99.7 and 98.6 percent utilization and the females given 100 and 200 mg. daily 99.3 and 92.6 percent utilization. In the second series, there was no difference in the efficiency of utilization of the thiamine in yeast and in the pure form, but the absorption of the thiamine from the yeast was from 6 to 11 percent less than in the case of pure thiamine. In the third, variations of as much as 82 percent in initial weights and 33 percent in gains in weight during the balance studies resulted in no noteworthy differences in absorption and utilization of the thiamine, average absorption values being 88.8 percent and utilization values 97.8 percent.

Growth of rats on synthetic diets containing limiting amounts of thiamine, J. M. McIntire, L. M. Henderson, B. S. Schweigert, and C. A. Elvehjem. (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc., 54 (1943), No. 1, pp. 98–100, illus. 1*).—The basal ration used was composed of casein, sucrose, salts, and corn oil, supplemented with adequate amounts of pyridoxine, riboflavin, nicotinic acid, pantothenic acid, choline, and halibut-liver oil. Without thiamine this ration failed to support growth and produced polyneuritic animals. No improvement was obtained with an addition of sulfited liver extract at the 2-percent level. In the presence of thiamine at levels of 0, 60, 80, 100, and 150 mg. per 100 gm. of ration, growth response was obtained; this growth response was further increased with rations supplemented with the sulfited liver extract in addition to the thiamine, the greatest increase occurring in the rats receiving 80γ thiamine per 100 gm. of ration. The addition of *p*-aminobenzoic acid and inositol to the synthetic ration also increased the rate of growth of rats receiving suboptimum levels of thiamine.

The relation of thiamine to blood regeneration, A. R. Maass, L. Michaud, H. Spector, C. A. Elvehjem, and E. B. Hart. (Wis. Expt. Sta.). (*Arch. Biochem., 4 (1944), No. 1, pp. 105–110, illus. 2*).—Using a technic similar to that reported for demonstrating the relation between riboflavin intake and hemoglobin regeneration (E. S. R., 91, p. 224), observations were made on young and adult dogs on a highly purified ration supplemented with the crystalline B vitamins, exclusive of thiamine. Blood analyses were carried out at various levels of thiamine feeding with and without phlebotomy. The bleeding produced anemia in all dogs, and inanition and loss of weight characterized the thiamine deficiency. Less than 10µg. thiamine per kilogram body weight was inadequate for maintaining body weight of adult dogs and did not permit weight increases in the puppies comparable to those attained by litter mates on higher thiamine levels. Anemia was not associated with the thiamine deficiency, and even when this deficiency was accompanied by the strain of phlebotomy there was no disturbance of the hematopoietic function. When inanition from the continued thiamine deficiency was associated with phlebotomy, some limitation of the hematopoietic ability of the animal resulted.

Nutritional studies in tuberculosis.—III, Thiamine (vitamin B_1) deficiency and peripheral neuritis, J. E. Farber and D. K. Miller (*Amer. Rev. Tuberc., 50 (1944), No. 3, pp. 229–233, illus. 1; Span. abs., pp. 232–233*).—Seven of the 400 tuberculous patients examined for niacin and riboflavin deficiency in the previous study (E. S. R., 91, p. 624) were found to have polyneuritis in varying degree. In addition to the neuritis, 3 patients had evidence of cardiovascular involvement and 4 showed deficiency of other vitamins of the B group. Improvement in the polyneuritis, except in patients with rapidly progressive tuberculosis, followed treatment with a liberal high vitamin diet together with at least 3 oz. of powdered brewers' yeast and 30 to 50 mg. of thiamine daily in divided doses. The improvement in the neuritis was slow, requiring several months in some cases.

Ascorbic acid content, color, and palatability of fresh and processed Swiss chard and beet greens, T. PORTER, D. M. SCHLAPHOFF, M. A. WHARTON, A. M. BRIANT, and R. M. BELTZ. (Mich. Expt. Sta.). (*Food Res., 9 (1944), No. 4, pp. 268–277*).—Leaves of Swiss chard (Fordhook and Rhubarb varieties) and beets (the common table beet, Detroit Dark Red variety; and the sugar beet, U. S. 200 × 215 variety), grown under known conditions, were harvested when they had attained partially mature growth and brought immediately to the laboratory for analysis and utilization. In the storage tests a portion of the freshly harvested leaves was rinsed in a tub of water, covered with wet burlap in bushel baskets, and allowed to stand at room temperature for 24 hr. These conditions were representative of local marketing practice. The leaves, both fresh and processed, were analyzed with midribs but without petioles. Reduced ascorbic acid, determined spectrophotometrically by the Morell method (E. S. R., 87, p. 15), averaged 35 and 39 mg. per 100 gm. of fresh leaves of the Fordhook and Rhubarb spinach, respectively, and 62 and 61 mg. per 100 gm. in the sugar-beet and table-beet leaves, respectively. Holding the greens for 24 hr. in the moist condition caused no significant loss of reduced ascorbic acid. The chards cooked by home-cooking procedures in an open pan in twice their weight of boiling water until done (7–8 min.) lost 74–88 percent of their ascorbic acid, while corresponding samples cooked 21–22 min. in a covered pan, without the addition of water except that left clinging to the leaves after washing, lost 93–95 percent; beet leaves cooked by these two procedures, respectively, lost 65–71 percent and 83–84 percent. These losses included the ascorbic acid that went into the cooking water, since the cooked greens were analyzed "as eaten." The greens cooked in the moderate quantity of water not only retained their vitamin values better but also had higher color and palatability scores than the greens cooked in a minimum quantity of water. Greens cooked in 8-lb. lots, in institutional preparation, followed by 10 min. of holding on the steam table, lost 77–85 percent of their ascorbic acid; after 60 min. on the steam table losses ranged from 87–97 percent, although there was no significant change in palatability score. In the cooking tests, both varieties of Swiss chard ranked higher on palatability scores than either the red-beet or sugar-beet leaves. Drying in a small home drier resulted in greens with very low, or no, reduced ascorbic acid content. These dried leaves were unpalatable when reconstituted and cooked. Alcohol-extracted pigment, determined by the method of Petering et al. (E. S. R., 83, p. 438), showed a highly significant correlation with either palatability or color as scored by the judges.

Ascorbic and dehydroascorbic acid in cooked garden beets, E. KELLY and F. W. CHRISTENSEN. (N. Dak. Expt. Sta.). (*Science, 100 (1944), No. 2594, p. 248*).—Beets of the Detroit Blood Red variety of the 1943 crop held in a ventilated vegetable storage cabinet from October 1943 to July 1944 contained 12.6 mg. of reduced ascorbic acid and 13.1 mg. of the dehydro form per 100 gm. fresh basis, as compared with 17.5 and 8.4 mg., respectively, for freshly harvested beets of the 1944 crop. These results, although based on different crops, suggest a considerable change of ascorbic acid to the dehydro form during storage, without any appreciable destruction.

Ascorbic acid value of the sweet potato as affected by variety, storage, and cooking, M. E. HOLLINGER. (La. Expt. Sta.). (*Food Res., 9 (1944), No. 1 pp. 76–82*).—After preliminary attention to the development of sampling details, ascorbic acid was determined in 25-gm. wedge-shaped samples taken from end to end of the unpared sweetpotato. Two such slices from each of five representative sweetpotatoes were extracted immediately with 3 percent metaphosphoric acid in a Waring blender and the extracts composited. Ascorbic acid was determined in the extract by titration with 2,6-dichlorophenolindophenol.

Ascorbic acid in four standard and three seedling varieties ranged from 0.235 mg. per gram for Triumph to 0.333 mg. per gram for Nancy Hall in samples taken during the first month after harvest. Tests suggested that the ascorbic acid content of the sweetpotatoes is a variety characteristic worthy of consideration in breeding. Varietal differences tended to become less significant after storage, however, since ascorbic acid decreased in storage and the losses were greater in varieties with higher initial ascorbic acid values. Losses ranged from 28–40 percent after 7-mo. storage (October to May) at 60°–80° F., and the ascorbic acid content of the potatoes then ranged from 0.166 mg. per gram for Triumph (5-mo. storage) to 0.203 mg. per gram for Nancy Hall.

Pared sweetpotatoes cooked by boiling in water or a sugar solution, and by steaming in a pressure saucepan, and samples baked and boiled without paring retained from 69–83 percent of their original ascorbic acid value. The highest retention was in the pressure saucepan. The lowest was in boiling after peeling; the presence of sugar in the boiling water exerted a favorable effect, however, and resulted in a 74 percent retention. In the boiling tests 15–19 percent of the ascorbic acid was found in the cooking water and about 11 percent was actually destroyed.

The content and stability of ascorbic acid in orange juice under home conditions, V. ROHRER and C. R. TREADWELL (*Tex. Rpts. Biol. and Med., 2 (1944), No. 2, pp. 175–182*).—Ascorbic acid was determined by the method of Harris and Oliver (E. S. R., 89, p. 625) in juice from oranges purchased on the retail market at Dallas, Tex., in January and February 1944. The method of reaming, whether with a hand reamer, a Universal press, or a Mixmaster, made little difference in the ascorbic acid content, juices freshly reamed by the several methods containing 0.5–0.7 mg. ascorbic acid per cubic centimeter. Storage in the refrigerator, either in an open or a closed container, had no significant effect on the ascorbic acid content of strained (through a wire-meshed strainer) or unstrained juice over a 24-hr. period; after 72 hr. of storage, however, the loss amounted to 20 percent. Dilution of the orange juice one-third with tap water did not hasten the destruction of ascorbic acid during refrigeration. Even storage at room temperature for 24 hr. or holding at 100° F. for 10 min. had little effect on the ascorbic acid content of the orange juice. Cut halves of oranges stored with cut surface exposed for 24 hr. in the refrigerator likewise showed but little loss of ascorbic acid as compared with control halves analyzed when the oranges were cut.

Vacuum sealing will retain vitamin C in evaporated milk, F. J. DOAN and D. V. JOSEPHSON. (Pa. Expt. Sta.). (*Food Indus., 16 (1944), No. 5, pp. 91–92, 136–137, illus. 2*).—In an effort to compensate for the previously observed loss of ascorbic acid in the processing and storage of evaporated milk (E. S. R., 91, p. 491), laboratory-prepared batches were fortified upon concentration, but before sterilization, with pure ascorbic acid as the rate of 50 mg./l. (to a final concentration of about 63 mg./l.) on a fluid-milk basis. The fortified milk, in 14.5-oz. cans, under vacuum seal or under nitrogen seal, retained the ascorbic acid pretty well, as much as 45 to 47 mg./l. fluid basis being retained even after 6 months' storage. Without this protective seal the normally sealed fortified milk lost ascorbic acid rather rapidly at first, dropping to about 39 mg./l. fluid basis in 1 mo. and gradually to about 34 mg./l. in 6 mo. The presence of excess air, as in normally sealed, underfilled cans, resulted in rapid and drastic reduction in ascorbic acid, not more than about 12 mg./l. fluid basis remaining after 6 months' storage. This was but little more than the amount found in normal milk under nitrogen seal (about 11 mg./l.). Preliminary trials showed that the nitrogen seal favored ascorbic acid retentions in normal evaporated milk. The advantages of sealing the fortified milk in the absence of air were carried over even after opening the can; such milk, held in the refrigerator in the can for 7 days after opening (by punching two holes in the top), still contained on an average 33.6 mg. ascorbic acid per liter, fluid basis.

The physiologic significance of vitamin C in man, M. PIJOAN and E. L. LOZNER (*New England Jour. Med., 231 (1944), No. 1, pp. 14–21*).—In this review the authors purposely limit the scope of the research covered to the examination of two theses "that the only known lesion caused by vitamin C deficiency is the scorbutic process; and that the evaluation of ascorbic acid deficiency in any given person from an assay of his usual diet is untrustworthy." From the evidence presented, covered by 87 citations including 3 references to unpublished work of the senior author, the following conclusions are drawn:

"The use of ascorbic acid, either synthetic or in the diet, is for the prevention or treatment of scurvy. With the possible exception of its influence on amino acid metabolism in premature infants, no other role can be ascribed to the vitamin. A diet cannot be condemned as deficient in this vitamin unless a continued linear decline of the content of the vitamin in the whole blood, white cell-platelet layer, or other tissue takes place, the appearance of scurvy being conclusive evidence. Relatively small amounts of the vitamin—possibly 25 mg. or under a day—are necessary to maintain fixed blood or white cell-platelet levels. Any fixed level of the vitamin in the plasma, irrespective of how little is present, indicates a non-scorbutic process and a positive body economy."

Some experiments on the possible relationship between vitamin C and calcification, G. H. BOURNE (*Jour. Physiol., 102 (1943), No. 3, pp. 319–328, illus. 10*).—Bone calcification, as indicated by pink coloration of newly deposited bone salt in animals receiving the dye sodium alizarin sulfonate, was followed in normal and regenerating bone of guinea pigs on a scorbutic diet with and without injected supplements of ascorbic acid. The regenerated bone was that formed after a 1-mm. hole was bored aseptically in each femur by the method described by Bourne (E. S. R., 89, p. 776). The deposition of bone salt in both the normal and regenerating bone was found to be retarded in scurvy, but administration of the pure synthetic ascorbic acid permitted the calcification to take place. The administration of vitamin P (citrin) and sodium citrate did not result in the formation of more osteoid trabeculae or the deposition of more bone salt than did ascorbic acid alone. Histological sections prepared without decalcification from pieces of rib (including the costochondral junction) taken from animals that had been kept on a scorbutic diet, with and without daily ascorbic acid supplements, were treated by Gomori's phosphatase technic. The black stain observed at sites of phosphatase activity indicated that the amount of phosphatase present in costochondral junctions was reduced in scorbutic animals. It is considered likely that one of the functions of ascorbic acid is to allow the production of a phosphatase-impregnated bone matrix upon which bone salt is deposited. Ascorbic acid may play some part in the formation or stabilization of alkaline phosphatase.

Effects of cecectomy, succinylsulfathiazole, and p-aminobenzoic acid on vitamin K synthesis in the intestinal tract of rats, H. G. DAY, K. G. WAKIM, M. M. KRIDER, and E. E. O'BANION (*Jour. Nutr., 26 (1943), No. 6, pp. 585–600*).—Young cecectomized rats on a basal diet free of vitamin K but containing yeast showed a high incidence of hypoprothrombinemia when fed 1 percent sulfasuxidine (**I**), whereas similar animals not receiving **I** and unoperated animals on the basal diet with **I** exhibited a low incidence of hypoprothrombinemia. The hypoprothrombinemia was readily alleviated by feeding 2-methyl-1,4-naphthoquinone. With adequate diet the cecectomized rats maintained good nutritional status. These results indicated that the cecum is an important site of vitamin K synthesis, but that this vitamin can be formed in other parts of the intestinal tract. Development of hypoprothrombinemia and restricted growth resulted when young rats on a purified diet containing B vitamins but no *p*-aminobenzoic acid (**II**) were fed 1 percent of **I**. Since addition of **II** markedly reduced these manifestations, it appeared that this compound counteracted the effect of **I** on vitamin synthesis in the intestinal tract.

TEXTILES AND CLOTHING

The utilization of wool by four saprophytic micro-organisms in the presence of additional nutrients, D. J. Hirschmann, M. Zametkin, and R. E. Rogers. (U. S. D. A.). (*Amer. Dyestuff Rptr., 33 (1944), No. 17, pp. 353–359, illus. 2*).—"The growth of four saprophytic micro-organisms, *Bacillus mesentericus, B. subtilis, Actinomyces albus* variety, and *Chaetomium globosum,* was studied by macroscopic and microscopic examination in the presence and absence of degreased, steam-sterilized wool fabric using the following liquid media: Czapek's, Czapek's without sucrose, Czapek's without $NaNO_3$, and Czapek's with both sucrose and $NaNO_3$ omitted. The same media were used in the solid form by adding agar to the various liquids. Distilled water and water agar were used as controls. Also the effect of adding an aqueous wool extract to the various liquid media was determined.

"Czapek's solution and Czapek's agar supported from good to excellent growth of the four organisms. In general, there was considerably less development in the incomplete Czapek's substrates than in the full Czapek's solution or agar but more than on the water agar. The latter supported either no growth or scant to fair growth. In distilled water, the micro-organisms did not grow except in the case of *C. globosum.*

"The four test organisms grew when the wool fabric or the wool extract was added to distilled water. The addition of wool fabric to Czapek's and the incomplete solutions stimulated the development of each organism in each media at some time during the incubation period. Also the presence of the wool extract enhanced the growth of each organism in Czapek's and the incomplete solutions.

"When the wool fabric was added to the solid media, microscopic examination revealed a stimulation of growth at the ends of the cut fibers on all media inoculated with *B. mesentericus* and *B. subtilis,* indicating diffusion of nutrients from the cut ends. Because of the preferential development of *C. globosum* and *A. albus* on the fabric, the stimulation at the ends of the fibers was not very apparent in these cases.

"Degreased, steam-sterilized wool, in the absence of added nutrients, was resistant to attack by three of the test organisms, namely *B. mesentericus, B. subtilis,* and *A. albus.* Under the conditions of these experiments only one organism, *C. globosum,* grew on the wool in the presence of distilled water alone. However, this growth was limited, being only fair at the end of the incubation period.

"*A. albus* grew on the wool in the presence of Czapek's and the incomplete Czapek's media and water agar and was the most active of the organisms in disintegrating wool fiber. Only in the presence of distilled water did this organism fail to grow or cause fiber damage. *C. globosum* grew on all the solid and liquid media and the controls but disintegrated the fiber less than *A. albus.* Only on Czapek's solution or agar did *B. subtilis* grow on wool and cause considerable fiber injury. *B. mesentericus* grew on the wool only on Czapek's agar in the test tube experiment and caused but slight fiber deterioration.

"Wool fiber is relatively resistant to the four test organisms. However, the soluble products resulting from the hydrolysis of wool are readily utilized by these organisms. The extent of fiber disintegration is influenced by the type of organism and the presence of added nutrients."

Resistance of fabrics and yarns to insect pests, J. R. BONNAR (*Amer. Dyestuff Rptr., 33 (1944), No. 13, pp. P266–P269*).—This report presents the results of cooperative tests for determining the degree of insect damage to treated and untreated fabrics. It was agreed "that the report of visual damage was the only reported damage which held true from laboratory to laboratory. It was agreed that within each laboratory the figures on either Excrement Weight Method or Fabric Loss Method did not vary greatly, but that the differences from one laboratory to another were too great for comparison."

Determination and evaluation of the resistance of textiles to insect pests, H. E. WILDE (*Rayon Textile Mo., 25 (1944), No. 9, p. 128*).—This report considers briefly the methods available for evaluating moth resistance of treated fabrics, the limitations of the methods, and the findings and conclusions of the various laboratories cooperating in a comparison of these methods. The visual method, certain details of which are outlined, was found the most satisfactory, as noted in the above report of the study. It is pointed out, however, that much work still remains to be done before final standards can be adopted.

Effectiveness and permanence of certain moisture-repellent and stain-resistant finishes, V. M. CROUCH and K. P. HESS. (Kans. Expt. Sta.). (*Rayon Textile Mo., 25 (1944), No. 9, pp. 103–105, 106, illus. 4*).—Of the two finishes tested one was a so-called permanent finish (I) produced by heating the fabric with a long-chain quaternary ammonium compound and the other was a wax-emulsion type of nonpermanent finish (II) applied during the laundering processes in a concentration of 2–6 oz. per gallon of water or precooked starch at a temperature of 100°–120° F. These two finishes were compared for their moisture-repelling and stain-resisting effects on two cotton poplins, a cotton broadcloth, and an organdy, and for their permanence to laundering and dry cleaning. The amount of moisture that passed through the fabric (rather than that absorbed by it) in definite periods of time, under known pressures, was taken as a measure of the water repellency of the fabrics and was measured by a modified wet disk method of water absorption. Moisture penetration and stain resistance of the fabrics were measured by means of a spray-device apparatus described and illustrated. A comparison of the physical characteristics of treated and untreated fabrics showed that (I) reduced the breaking strength and stretch of the fabric, but that this was not true of (II).

Finishes (I) and (II) imparted equal water-repellent and stain-resistant properties to the fabrics but varied in their permanence under laundering and dry-cleaning processes. The high degree of repellency imparted to the fabrics by (I) was not noticeably reduced in 10 launderings, but resistance to moisture and stain decreased markedly after 5 dry cleanings. Originally, however, this finish gave the fabric a high degree of resistance to staining with coffee and grape juice but not to ink. The slight staining from coffee and grape juice was easily removed from the dry-cleaned portions.

The repellency imparted to the fabrics by (II) was destroyed by 10 launderings and 5 dry cleanings. Stains caused by coffee and grape juice were removed by rinsing in cold water; stains in the dry-cleaned fabrics were most difficult to remove. Ink stains in all fabrics resisted removal by rinsing in cold or hot water and by home laundering in warm soapsuds; commercial laundering was required for ink-stain removal. This latter treatment removed the moisture-repellent properties of (II) but had little effect on (I).

Rayon—a product of American chemurgy, L. WHITNEY (*Rayon Textile Mo., 25 (1944), No. 9, pp. 59–62, illus. 1*).—This is a summary of recent events in the rayon industry, including the development of new war uses for rayon.

Serviceability of linen, cotton with a permanent finish, and rayon/cotton table napkins, L. E. SUMNER and E. D. ROSENBERRY. (Purdue Univ.). (*Rayon Textile*

Mo., 25 (1944), No. 8, pp. 53–56).—"Linen, cotton with a permanent finish, and rayon and cotton napkins, at different price levels, were put into service in a college dining hall where they were used over a period of 32 weeks, during which time each napkin was used by one person for 3 days of each week and then laundered in the school laundry.

"The deterioration was greatest in the linen napkins, as is indicated by both loss in breaking strength and weight per square yard. This is probably due to the brittleness of the fiber which causes it to slough-off in laundering. The amount of deterioration that takes place, and the appearance of the linen napkins after use, seem to depend to a great extent on the quality of the fibers which are used in constructing the napkin. In general, deterioration, as measured by loss in breaking strength, was less in the cotton fabrics with the permanent finish than in the linen fabrics. The finish was still effective in preventing linting and in giving a firm handle to the fabric after 32 launderings. It had an appreciable effect in decreasing the strength losses of cotton yarns during use, as indicated by a comparison with the cotton yarns of rayon and cotton fabrics which had no finish. This study, however, does not show that the permanent finish prevented or decreased shrinkage of the cotton napkins.

"The rayon and cotton napkins gave satisfactory wear, were cheaper than the linens, and would give longer wear if the hems had been of better workmanship. The most expensive and the one judged to be the best quality from its construction and laboratory performance was just as attractive after 32 launderings as when new, and it showed less deterioration in either its cotton or rayon yarns than any other fabrics, judged by loss in breaking strength. The rayon yarns of all of the rayon and cotton fabrics resisted deterioration more than the cotton and linen yarns used in the fabrics in this study.

"The shrinkage in laundering of the fabrics under laboratory conditions did not predict the shrinkage under actual laundering conditions which existed in the college dining hall. Even though the temperature of the water was higher by approximately 50° in the laboratory laundering, the shrinkage was not as great."

Sterilization in the power laundry, J. F. OESTERLING, C. R. PHILLIPS, J. F. KRAWIEC, P. B. MACK, M. A. FARRELL, and S. HOYNAK (*Pa. State Col. Bul., 37 (1943), No. 32, pp. 10+*).—Experimental tests and commercial and institutional trials showed that in laundry practice soap and water at high temperatures, sodium hypochlorite in small concentrations, and the ordinary laundry souring agents (acid sodium fluoride or acetic acid), as well as special sterilizing sours, all induced a sterile condition in fabrics and textiles contaminated with the general run of bacteria. A combination of soap and water, at high temperature, and either sodium hypochlorite or sour or both produced complete destruction of the bacteria present. Soap and an alkaline builder in concentrations and at temperatures commonly used in the power laundry were found to be germicidal agents for the three pathogenic organisms tested (*Staphylococcus aureus, Eberthella typhosa,* and *Clostridium welchii*). Sodium hypochlorite or hydrogen peroxide in low concentrations as used with soap in power laundry procedure also produced complete destruction of these organisms. Water at 160° F. produced complete or almost complete destruction in the three cases, but laundry sour was a good sterilizer with *E. typhosa.* The general procedure recommended for the use of commercial and institutional laundries, namely, an initial suds with a low titer soap, three or four heavy suds baths with high titer soap, with low concentrations of an oxidizing agent such as sodium hypochlorite or hydrogen peroxide in the last suds, followed by a series of rinses, with or without a souring bath, was found to produce complete destruction of the bacterial organisms ordinarily encountered and of the three pathogenic organisms studied.

The value of dry-cleaning to public health (*Pa. State Col. Bul., 37 (1943), No. 26, pp. 4+*).—The sterilizing effect attained after various stages in the standard dry-cleaning procedure was investigated with test squares of new wool originally not sterilized and of new wool originally sterilized by the method of Humfield et al. (E. S. R., 78, p. 432) and then inoculated with *Eberthella typhi* or *Diplococcus pneumococci* prior to dry cleaning. Following the various steps of the dry-cleaning process, the test squares were dipped in 9 cc. of sterile water, which was then plated out and examined to determine plate counts of bacterial colonies developing. From the percentage reduction in bacterial count following the various treatments it was apparent that the complete dry-cleaning process, involving the use of a dry-cleaning soap, rendered the textile fabrics sterile to the general run of contaminating bacteria, as present on the unsterilized wool, and to the pathogenic organisms as well. Neither heat alone at the temperature most commonly used in drying fabrics during dry cleannig (120° F.) nor dry-cleaning solvent (Stoddard Solvent) without soap or other detergent was effective in producing complete sterilization. A sulfonated oil type of detergent or the usual oleate dry-cleaning soap produced complete sterility in combination with the standard dry-cleaning procedure. It is concluded, therefore, that dry cleaning must be regarded as of value to public health.

Dresses and aprons for work in the home, C. L. Scott and E. Bruzgulis (*U. S. Dept. Agr., Farmers' Bul. 1963 (1944), pp. 16, illus. 33*).—The dresses and aprons, designed to meet the requirements of actual use, permit of free action; offer safety features for work around the stove, for stooping, and for getting up and down on chairs or ladders; and offer time and energy-saving features that make the garment quick and easy to put on and to iron. Useful pockets, placed within convenient reach, and simplicity and attractivenesss are the additional features. It is noted that commercial companies have reproduced these designs in patterns, thus making them available to home sewers.

HOME MANAGEMENT AND EQUIPMENT

Lighting the home with liquid fuels, L. J. Peet and R. P. Koch. (Iowa State Col.). (*Jour. Home Econ., 36 (1944), No. 6, pp. 354–358*).—In this study of the adequacy of liquid fuel lamps usually obtained on the market, three types of lamps with a variety of shades were used in measurements with a Weston Sight Meter of illumination under the lamps. These included (1) mantle-wick kerosene-burning lamps, comprising two table lamps of different heights, a bracket lamp, a hanging lamp, and a floor lamp; (2) mantle-wick vapor-pressure lamps, including one using kerosene and one gasoline as fuel; and (3) straight- and round-wick kerosene lamps, including two table and one bracket. In addition to laboratory tests, selected lamps were taken to a home where electricity was used to light the living room and readings were taken for comparison with IES electric lamps. Various combinations of lamps were also tested in this home and in a rural home where electricity was not available.

Practical recommendations for manufacturers resulting from the study are to (1) use more heat-resistant material for the handles by which the flow of the vaporized fuel in the vapor-pressure lamps is regulated, and (2) continue making shades of fire-resistant material but provide white linings and large lower diameters. Recommendations to consumers are to use shades on all lamps to eliminate glare and increase illumination under the lamp, to select shade materials and a form of construction facilitating cleaning, to keep vapor-pressure lamps pumped to the highest pressure possible, and to turn the wicks of mantle-wick lamps as high as possible without causing blackening of mantle. "For a 200-sq.-

ft. floor area in a room used for general living activities use a minimum of three shaded lamps, one for general illumination, the other two for local light—two mantle-wick lamps and one vapor-pressure lamp, or one mantle-wick, one round-wick, and one vapor-pressure lamp."

REPORTS AND PROCEEDINGS

[Annual reports of the North Dakota Agricultural Experiment Station, 1938, 1939, 1942, 1943] (*North Dakota Sta. Rpts. 1938, pp.* [*21*]; *1939, pp.* [*21*]; *1942, pp. 31+*; *1943, pp. 34+*).—These mimeographed reports include for 1938 and 1939 only administrative information; those for 1942 and 1943 also report progress results for the respective years, for the most part previously noted.

Report of agricultural research and other activities of the Western Washington Experiment Station for the fiscal [years ended March 31, 1941, and March 31, 1942], J. W. KALKUS ET AL. (Partly coop. Wash. Expt. Sta. and U. S. D. A.). (*Western Washington Sta. Rpts. 1941, pp. 70, illus. 1; 1942; pp. 70*).—These reports give brief summaries of research work and other activities carried on, respectively, for these fiscal years, together with results for some projects for the following summer seasons.

The data for 1941 include results in agronomy with alfalfa inoculation and variety tests, hay ventilation, selections of grasses and legumes, hardiness in oats, control of Bracken fern, and culture of flat peas and pyrethrum; in dairy husbandry, with analyses of hays, silages, and pasture grasses, measures of pasture yields, liquid manures and fertilizers for pastures, stack silage, and roughage v. roughage plus concentrates for dairy cattle; in entomology, including the control of the cherry fruitworm, holly insects, Lecanium scale on sour cherries, and pear thrips; in horticulture, including breeding of strawberries, raspberries, blackberries, and dewberries, variety tests with peaches, blueberry investigations, freezing studies with peas and sweet corn, varieties of potatoes, sweet corn, and melons, and vegetable seed production; in plant pathology, including bulb diseases, raspberry mosaic, brown rot of stone fruits, net necrosis, bacterial ring rot of potato, cabbage seed diseases, and running-out diseases of strawberries; in poultry husbandry, including disease resistance, feeding and management, vitamin A requirements of laying hens, effect of salt on cannibalism, inheritance of slow feathering and eggshell quality, and yolk absorption in chicks; in soils, including phosphates for western Washington, fertilizers and inoculants for freezing and canning peas, boron deficiency of alfalfa, fertilizers for potatoes and small-grain hays, potash deficiency of Blue Lake beans, and soil adaptability and fertilizer studies; and in veterinary science, including work with fowl pox, feeding a 32-percent mash to pullets artificially infected with intestinal coccidia, and leucosis in poultry.

The data for 1942 include results in agronomy, including variety tests and boron deficiency tests with alfalfa and other crops, Russian dandelion plantings, fertilizer placement and rates for peas, table beets, spinach, carrots, sweet corn, and potatoes, inoculation of canning and freezing peas, and phosphates for western Washington soils; in dairy husbandry, including work with proved sires, liquid manures and supplements for pastures, roughage v. roughage plus concentrates for dairy cattle, and preserving roughages in the farm silo; in entomology, including the control of the pear thrips, cherry fruitflies, cabbage seed weevil, *Sitona* weevil (*S. lineata*), and bulb flies and mites; in horticulture, including breeding strawberries and raspberries, blackberry hybrids, peas, and potatoes, varieties of potatoes, peaches and other fruits, and nuts, propagation of trees and shrubs by cuttings, and seed production of cabbage and beets; in plant pathology, including cabbage seed diseases, raspberry mosaic, bulb diseases, footrot of peas, and running-out diseases of strawberries; in poultry husbandry, including studies of disease resistance, effect of salt on cannibalism, feeding and management of breeding hens (including riboflavin supplements) and laying hens (including vitamin A requirements), development of new chick rations, inheritance of eggshell quality, egg dehydration, and methods of "blacking-out" poultry houses; in veterinary science, including avian leucosis, treatment of infectious coryza in chickens with sulfathiazole, efficiency of a delousing leg band, and erysipelas and fowl pox in turkeys; and grazing studies on cutover lands, including a test with Elbe flat peas.

MISCELLANEOUS

A source-book of biological names and terms, E. C. JAEGER (*Springfield, Ill.: Charles C. Thomas, 1944, pp. 256+, illus. 94*).—This lists alphabetically fully 12,000 elements from which biological names and terms have been derived, together with their origins, meanings, and many examples of their use.

Biology as an approach to a sound philosophy, C. C. DOAK. (Tex. A. and M. Col.). (*Tex. Acad. Sci. Proc. and Trans., 27 (1943), pp. 73–79*).

Five and fifty years, 1888–1942, J. L. HILLS (*Vermont Sta. Bul. 515 (1944), pp. 56, illus. 16*).—This is a history of the Vermont Station, developed and enlivened by the author's long and intimate association and leadership (E. S. R., 86, p. 433). Considerable little-known material relating to the pre-Station period has been included.

Bimonthly Bulletin, [September-October 1944] (*North Dakota Sta. Bimo. Bul. 7 (1944), No. 1, pp. 26, illus. 3*).—In addition to articles noted elsewhere in this issue, this number contains Agricultural Changes Elsewhere Affect North Dakota Agriculture (p. 2) and A Look Ahead—The Weather and the 1944 Grain Crop and How It May Affect the 1945 Grain Crop (pp. 3–4), both by H. L. Walster; Flax, Wheat, and Chromosomes, by L. R. Waldron (pp. 4–5); Palatability of Grasses Grown at Mandan, North Dakota, by H. L. Walster (pp. 6–7) (coop. U. S. D. A.), an abstract of an earlier article by Rogler (E. S. R., 91, p. 674); and Report of the Veterinary Diagnostic Laboratory, July 1, 1943-June 30, 1944, by J. O. Foss (pp. 14–17).

NOTES

Connecticut State Station.—Lt. Col. M. F. Morgan, chief agronomist since the organization of the department in 1923 and on military leave since 1942, was killed in action on the island of Leyte on January 15. He had previously served in World War I, receiving both the Distinguished Service Cross and the Croix de Guerre.

Born in West Virginia in 1895, he had graduated from the West Virginia University in 1920, and subsequently received the M. S. and Ph. D. degrees from Ohio State University. Before coming to Connecticut he had served on the soils staffs of both of these institutions, and from 1927 to 1933 was also associate professor of forestry in the Yale School of Forestry. He had achieved much distinction as a research agronomist, both as the author of the widely known Morgan method of soil testing and for his contributions to soil classification, lysimeter investigations, and microchemical soil tests, forest soils, and the utilization of fertilizers by tobacco and vegetable crops. He was president of the Soil Science Society of America in 1933 and had been secretary of Section O (Agriculture) of the American Association for the Advancement of Science since 1936.

Illinois University.—Dr. William Trelease, emeritus professor of botany since 1926, died on January 1 in his eighty-eighth year. He came to the university in 1913 and had also been associated with the U. S. Department of Agriculture as a special agent on cotton insects, the University of Wisconsin, Harvard University, Johns Hopkins University, and Washington University of St. Louis, where he opened the Shaw School of Botany in 1885 and served as director of the Missouri Botanical Garden from 1889 to 1912. He was the first president of the Botanical Society of America in 1894–95 and was again president in 1918. Among his many publications were his manuals on Plant Materials of Decorative Gardening (1917), Winter Botany (1918), and The American Oaks (1925).

Kansas College.—In conformity with the efforts of the Office of Defense Transportation to restrict travel, the 1945 Farm and Home Week scheduled for February 6–9 was canceled, causing the second omission of this series since the opening of Farmers' Institutes in 1877. In its stead a Farm and Home Week of the Air was presented beginning February 6.

Kentucky Station.—Dr. Clifford Westerfield has been appointed associate animal pathologist.

Michigan College and Station.—An Institute of Nutrition has been established, with an administrative committee consisting of C. F. Huffman, professor of dairying as chairman, Dean R. C. Huston of the Graduate School, Director V. R. Gardner of the experiment station, Margaret A. Ohlson, head of the department of foods and nutrition, and C. L. Cole, C. A. Hoppert, and W. L. Mallmann, professors, respectively, of animal husbandry, biochemistry, and bacteriology. Its objectives are outlined by the committee as (1) to better establish the college as a research center of foods and nutrition, (2) to provide an organization for graduate training in foods and nutrition, and (3) to better serve the consumer, the farmer, and the feed and food industries. It is planned to coordinate and integrate instruction and research in nutrition and to supply a contact between the college and industry. The institute will receive aid for maintenance from the college, and it is hoped that industry and trade and agricultural organizations will provide grants for research and industrial fellowships.

New Mexico College and Station.—Clarence P. Wilson, associated with the college since 1912 and station editor since 1925, died January 19 at the age of 66 years. A native of Missouri, he was graduated from the college in 1908 and received the M. S. degree in 1911. He had been especially interested in problems of range improvement.

New York State Station.—Arthur W. Clark, retired on December 31, 1944, as professor of chemistry after a continuous service since July 1, 1905. He had been in charge since 1914 of the chemical inspection of commercial feeding stuffs and fertilizers.

North Carolina College and Station.—Dr. R. W. Cummings, head of the department of agronomy, has also been appointed assistant director of the station. Dr. C. H. Bostian, professor of zoology and associate in poultry genetics research, has been made assistant director of instruction in the College of Agriculture. Other appointments include James H. Hilton, assistant chief of the department of dairy industry in the Indiana Station, as head of the department of animal industry; James H. Jensen, associate professor of plant pathology in the University of Nebraska, as professor and head of the section on plant pathology; John Willis Weaver, Jr., as associate in agricultural engineering in the station; and H. Brooks James as associate in agricultural economics in the station.

Oklahoma Station.—A grant of $20,000 from commercial sources has been received for research on the mineral requirements of range beef cattle. This will be used to expand work on this subject now under way on the station's 4,500-acre experimental range near Stillwater and to check the results in other parts of the State.

Pennsylvania College and Station.—Dr. Dennis E. Haley, professor of soils and phytochemistry, died February 10 at the age of 59 years. A native of Ohio, he received from the Ohio State University the B. S. degree in 1913 and the Ph. D. degree in 1932. He has been associated with chemical research in Pennsylvania since 1914, working on problems in agricultural chemistry and biochemistry, notably with tobacco, soil potassium, and castor-bean lipase.

Dr. Donald V. Josephson, assistant professor of dairy manufactures, has been appointed associate professor of dairy technology in Ohio State University.

Utah College and Station.—Recent appointments in animal husbandry include Dr. Louis L. Madsen, nutritionist with the U. S. D. A. Bureau of Animal Industry, as head of the department; Dr. Lorin E. Harris, research instructor in animal nutrition in the Cornell Station, as associate professor; and Dr. Carroll I. Draper, associate professor of poultry husbandry in the University of Hawaii, as associate professor of poultry husbandry.

Washington College and Station.—Dr. Wilson Compton has assumed the presidency of the college.

The resignations are noted of Carl N. Berryman and William A. Harvey as assistants in agricultural economics and agronomy, respectively, the former to accept a commercial position in Yakima, Wash., and the latter a position with the California Station. Recent appointments include Walter M. Bristol as field assistant in agricultural economics; J. Frank Cone as assistant dairy husbandman; Dr. Hazel Cushing as specialist in family living and child development; W. H. Johnson as instructor in agricultural engineering vice O. J. Trenary resigned to accept a commercial position; Dr. James McGinnis as assistant poultryman and assistant chemist; and Dr. E. H. Peterson as associate veterinarian.

Wisconsin University and Station.—Dean and Director E. B. Fred of the College of Agriculture and Station has been appointed president, effective February 15.

Wyoming Station.—Under an Act of Congress approved December 15, 1944, 24 acres of land at Powell belonging to the Federal Government have been transferred to the station for use as an agricultural experiment substation.

U. S. Department of Agriculture.—Dr. E. C. Auchter, Agricultural Research Administrator, has been appointed director of the Hawaiian Pineapple Research Institute and has been succeeded by P. V. Cardon, formerly Assistant Administrator.

David Lumsden, from 1922 until his retirement in 1941 a horticultural inspector for the Bureau of Entomology and Plant Quarantine in connection with the identification and handling of plant material, died January 22 in his seventy-fourth year. A native of England and with many years of practical experience as a landscape architect, he served as instructor in horticulture and landscape art in the New Hampshire University from 1908 to 1914 and as assistant professor of floriculture in Cornell University and the Cornell Station from 1914 to 1919 and as director of agricultural reconstruction and landscape architecture at Walter Reed General Hospital from 1919 to 1922. Some of his best known research work was with fertilizers for carnations and the breeding of orchids.

Brazilian National Agricultural Center of Education and Research.—This comprehensive project, which has been under development for 6 years, was scheduled to be opened early in 1945. Commonly known as "Kilometer 47" because of its distance from Rio de Janeiro, the center will comprise Brazil's largest agricultural experiment station, an agricultural college, a boys' training school, and many special educational projects. The National School of Agronomy and the National School of Veterinary Medicine, now scattered over the city of Rio de Janeiro, will be transferred to the center, as well as a number of research laboratories including the Institute of Ecology and Agricultural Experimentation, the Institute of Agricultural Chemistry, the National Institute of Oils, and the Institute of Fermentation. The Agricultural Institute will be coordinated with the various Federal agricultural institutes which conduct a series of experimental stations in Brazil.

A tract of 10,750 acres has been set aside for the center, of which 310 are in experimental plantings of fruits, cereals, fiber plants, oil-bearing shrubs and trees, and forest trees. Laboratories are already operating in the departments of silk culture, poultry, apiculture, farm mechanics, meteorology, and biology. Some buildings are occupied, and others are being completed, including a central building covering with its patio about 2.5 acres, with facilities to accommodate 1,200 students.

☆ U. S. Government Printing Office: 1945—628857

Attempts to isolate the suspected causal organism were inconclusive. *Leptospira* were present in focal accumulations in certain organs, although also scattered outside the main organic foci. The association of massive foci of *Leptospira* with the principal pathologic changes is believed to characterize the reported cases as bovine leptospirosis.

The features of early mastitis in heifers during the first lactation, J. F. MALCOLM, C. W. KING, and M. M. CAMPBELL (*Vet. Rec., 56 (1944), No. 27, pp. 227–230*).—To obtain information as to the etiology of bovine mastitis, 28 heifers in a tuberculin-tested herd were kept under clinical observation throughout their first lactation, and specimens of milk from individual quarters were examined at weekly or fortnightly intervals for leucocyte content, electrical conductivity, and specific pathogens. Twelve of the heifers remained normal and without any evidence of mastitis throughout the lactation, although *Staphylococcus aureus* or *albus* was occasionally found in the milk of one or two quarters, and similarly *S. agalactiae* in one instance. Four heifers showed various abnormal conditions of the udder which appeared to be due to lactational or other factors of a nonspecific nature. Twelve other heifers developed mastitis or udder disturbances during the lactation, 8 being clinical cases and 4 subclinical. In all, *S. aureus* or *albus* was found at some time or other in the milk of the affected quarters, but in only 5 heifers were these staphylococci found so frequently or in such numbers as to indicate the possibility of a staphylococcal infection. In 5 of the remaining 7 cases no staphylococci could be found even by enrichment methods in the milk of the affected quarters for a period of 1 to 3 mo. after the initial rise in cell count and conductivity, which were the first indications of disease. In spite of the fact that *S. agalactiae* was associated with cases of mastitis in the older cows of the herd during the same period and the organism was found occasionally in the milk of the heifers, there were no cases attributable to *S. agalactiae* among the heifers. Other specific pathogens (streptococci, corynebacteria, and coliform bacteria) were also absent from the milk, and, therefore, the primary agent of infection in these cases remained in doubt.

Mastitis control by vaccination, C. R. CORSON (*Vet. Med., 40 (1945), No. 1, p. 24*).—The author reports an experiment in mastitis control through immunization undertaken in 20 dairy herds comprising 368 cows. Ten herds, including 181 cows, were vaccinated with mixed bacterins, and 10 herds, comprising 187 cows, were given lactovaccine. Over a period of several years prior to the beginning of the experiment the number of cases of acute and chronic mastitis in these 20 herds had averaged 8 cases per herd per year. During the 6-yr. period of the experiment no new cases of acute mastitis developed in the 10 herds given lactovaccine, except in new cows added to the herds, but 10 cases of chronic mastitis were found. In the 10 herds treated prophylactically with mixed bacterins, an average of 4 cases per herd per year occurred, some of them acute.

Water as a vehicle for the infusion of sulfanilamide in the treatment of mastitis, C. B. KNODT and W. E. PETERSEN. (Minn. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc., 105 (1944), No. 811, pp. 212–214, illus. 2*).—Although based on only a limited number of acute and chronic cases of mastitis, a method is presented which uses water as the vehicle for the infusion of sulfanilamide into the bovine mammary gland. As much as 60 gm. of sulfanilamide, shaken with 600 cc. of distilled water, was injected into completely milked quarters with promising results.

Treatment of necrophorus infections of cattle with sulfapyridine, H. S. KINGMAN and W. M. STANSBURY (*North Amer. Vet., 25 (1944), No. 11, pp. 671–674*).—This report records clinical experiences with sulfapyridine in the treatment of necrotic laryngitis and interdigital phlegmon in cattle.

Bovine trichomoniasis, B. B. MORGAN (*Minneapolis 15: Burgess Pub. Co., 1944, pp. 150+, illus. 7*).—One purpose of this monograph is primarily to assemble in convenient form all available information related to bovine trichomoniasis and secondarily to stimulate research workers in related fields. The several chapters deal with the morphology and life cycle, isolation, cultivation, symptoms and lesions, diagnosis, serology, immunity, H-ion concentration, animal experimentation, prevention and control, and miscellaneous. A bibliography of 408 titles and a parasite-host list of 91 *Trichomonas* are included.

The intradermal test in bovine trichomoniasis, W. R. KERR (*Vet. Rec., 56 (1944), No. 34, pp. 303–307*).—Some applications of this test are described, and its limitations are discussed.

An outbreak of bovine tuberculosis due to udder irrigation, D. MCFARLANE, J. S. GARSIDE, P. S. WATTS, and J. T. STAMP (*Vet. Rec., 56 (1944), No. 41, pp. 369–371*).—An outbreak of tuberculosis in an attested herd suggested that the high incidence had resulted primarily from irrigation of the udders with apparatus contaminated with *Mycobacterium tuberculosis.* Investigation revealed that irrigation was responsible for the introduction of tubercle bacilli and subsequent development of tuberculous mastitis in each of the 7 irrigated quarters of 6 cows in a single herd. Fourteen additional quarters in the same herd, irrigated with the same apparatus and on the same day, developed a clinical condition similar to and probably identical with those examined. Every animal in contact with those irrigated developed tuberculosis, as shown by the tuberculin test. Thirteen of 14 calves fed on bulked milk from this herd developed a positive tuberculin reaction. Three yearlings, running with the cows when dry gave positive tuberculin reactions, probably from sucking the irrigated udders. The ease of infection of the bovine mammary gland with *M. tuberculosis* is pointed out, and the great danger of mammary tuberculosis to the "in contacts" is emphasized, as well as the frequent impossibility of clinical diagnosis of tuberculosis of the bovine mammary gland and the necessity for taking adequate precautions when irrigating udders.

A consideration of some of the factors concerned in intracutaneous injection of cattle, W. M. HENDERSON (*Jour. Pathol. and Bact., 56 (1944), No. 3, pp. 315–325, illus. 6*).—The pressure required for the intracutaneous injection of cattle is affected by the choice of site and by the volume and viscosity of the inoculum. The pressure required for the injection of 5 cc. of a watery inoculum into the skin of the neck of cattle may be as great as 30 lb. per square inch. This pressure has to be increased for the injection of more viscous liquids. A description is given of the design and use of a syringe which enables an intracutaneous injection of up to 10 cc. of liquid to be made at a single site. Details are given of experiments which demonstrate the rapid absorption by the lymphatics of material injected intracutaneously. A comparison is made of the rate of lymphatic absorption after subcutaneous injection. The opinion is expressed that, because of the more exacting technic required, the production of immunity by intracutaneous injection is not advisable unless this route is proved to give better results than the subcutaneous or intramuscular.

A case of choline poisoning in cattle, A. BONDI and H. MEYER (*Nature [London], 154 (1944), No. 3913, pp. 551–552*).—Pathological symptoms observed in cattle at Kiriat Anavim, Palestine, in which after the first calving the uterus did not contract but remained open and atonic for a considerable time, were attributed in the absence of other observable causes to the feeding of wet brewers' grains. Analyses of this material yielded 0.25–0.28 percent free choline (calculated as dry matter). Normal barley contained no free choline, and it is concluded that "free choline can act as a poisoning agent when fed over long periods of time."

Mushroom poisoning in cattle, P. L. PIERCY, G. HARGIS, and C. A. BROWN. (La. State Univ.). (*Jour. Amer. Vet. Med. Assoc., 105 (1944), No. 811, pp. 206–*

208).—Following the death of several cattle from suspected poisoning on range pastures, investigation revealed that an extremely dry and warm summer followed by heavy drenching rains in mid-September had made conditions ideal for mushroom growth and that certain wooded areas had become literally white with mushrooms, including an unusually large number of the destroying angel (*Amanita verna*). Experimental feeding with this fungus revealed that neither a calf nor a rabbit ate the mushrooms voluntarily, but cattle in the areas ceased to be affected when the mushrooms practically disappeared. It is believed that in view of the infrequence of the prevailing conditions, the danger of poisoning by mushrooms is minimal, particularly if range cattle are maintained on ample and nutritious forage.

Sugar beet poisoning in cattle, F. CHAMBERS (*Vet. Rec., 56 (1944), No. 16, p. 128*).—Three outbreaks ascribed to the feeding of whole beets are described.

The control of diarrhea ("white scours") of new-born dairy calves by means of serum and sulfaguanidine, G. H. WISE and G. W. ANDERSON. (S. C. Expt. Sta.). (*Jour. Dairy Sci., 27 (1944), No. 11, pp. 965–979, illus. 1*).—An acute infectious and contagious diarrhea (white scours) of newborn dairy calves was investigated clinically.

Scrupulous sanitation of the surroundings and adequate nutrition of the calf during the immediate postnatal period are regarded as fundamental in the control of scours of newborn calves, but such measures alone were not found adequate to control the disease under general herd conditions. No recognizable reduction in the incidence of scours resulted from either giving cod-liver oil as a dietary supplement or injecting a commercial antiscour serum as a prophylactic measure.

In further studies with sulfaguanidine (E. S. R., 87, p. 854), it was found to be effective prophylactically and therapeutically when given in proper doses.

"As a prophylactic agent, it is recommended that sulfaguanidine in doses of approximately 2 gm. be given to the calf at the following intervals: First dose, shortly after first colostrum consumption, which should not be later than 2 hr. after birth; second dose, 6 to 8 hr. later; subsequent doses, morning and night through the second or third day. Doses may be reduced to 1 gm. after the first 36 hr.

"The following amounts of sulfaguanidine, per 100 lb. body weight of calf, given at 4- to 6-hr. intervals are recommended as a guide for treatment: First dose, 7 gm.; second dose, 5 gm.; third and subsequent doses, 4 gm. These doses should be varied according to the condition and response of the calf. During the first 24 hr. after the first clinical symptoms of scours are manifested, all feed should be withheld from the calf and liberal amounts of warm water should be given. Discontinue the sulfaguanidine therapy as soon as scours subsides.

"In view of the dangers from complications associated with diarrhea of the newborn calf, prophylactic measures should be given precedence over therapeutic control except in herds where only sporadic cases occur."

A list of 37 references is appended.

Vaxartad muskeldegeneration (s. k. fiskkött) hos kalv [Waxy muscular degeneration (so-called "fish flesh") in calves], K. LILLEENGEN (*Svensk Vet. Tidskr., 49 (1944), No. 8, pp. 231–289, illus. 4; Eng. abs., pp. 284–288*).—The etiology and pathogenesis of this disease are discussed on the basis of studies with newborn calves fed on milk in which the greater part of the A, B_1, and C vitamins had been destroyed by long-continued heating and oxidation. These experiments have indicated that the source of the disease is not to be sought for in infections or traumatic causes, but is more probably ascribable to C or B_1 hypovitaminosis or to a combination of these factors.

Blindness with papilledema in calves, E. L. STUBBS (*Jour. Amer. Vet. Med. Assoc., 105 (1944), No. 811, pp. 209–211*).—A number of cases are cited in a single herd which were diagnosed as typical of choked disk or papilledema. Although available information does not show that such blind animals give birth to similarly affected animals, their use for breeding purposes is deprecated and the use of the best possible feeding methods recommended to prevent the development of blind calves.

Listerellosis occurring in Wisconsin, G. R. Spencer, H. H. Hoyt, and C. K. Whitehair. (Wis. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc., 105 (1944), No. 811, pp. 195–197, illus. 4*).—Outbreaks of listerellosis in three Wisconsin flocks of sheep are described. The symptoms, post-mortem gross and microscopic tissue changes, and bacteriologic findings are reported.

Ulcerative stomatitis in sheep, A. M. McDonald (*Vet. Rec., 56 (1944), No. 36, pp. 324–325*).—Infections in two flocks of ewes and lambs are described, together with an apparently satisfactory response to sulphonamide therapy.

Control of blowfly on Merino sheep: Classification of types as a measure in breeding less susceptible sheep, A. H. de Vries and J. C. de Klerk (*Farming in So. Africa, 19 (1944), No. 221, pp. 485–495, illus. 14*).—Continuing the series (E. S. R., 90, p. 81), a detailed description is given of three types of sheep, classified as to skin development in the crutch, as a measure in breeding sheep less susceptible to blowfly attack.

Nicotine poisoning in lambs, H. A. Crawshaw (*Vet. Rec., 56 (1944), No. 31, pp. 276–277*).—The death of eighteen 3-month-old lambs, with an average weight of 37.2 lb., as a result of overdosing with a nicotine sulfate, copper sulfate solution is recorded. Ante-mortem symptoms and post-mortem findings are described, and it is concluded that the toxic dose of nicotine sulfate for lambs of this class lies between 3.2 and 4.8 gr., which is approximately equivalent to from 0.64 to 0.96 gr. of nicotine. A report is recorded that 16–gr. doses of nicotine sulfate (3.2 gr. of nicotine) was the dose required to produce toxic symptoms in bulls and heifers of from 1 yr. to 18 mo. of age.

Diagnostic tests including hemotology in swine brucellosis and capsule formation in Brucella, C. M. Cotton (*Md. Univ. Off. Pub., 41 (1944), No. 6, pp. 9–10*).—A study of capsules in 38 strains of *Brucella* showed all organisms to be encapsulated, but there were definite differences in rough, smooth, and intermediate strains when stained with India ink-crystal violet capsular stain, and the microscopic method of identifying these strains appeared to be easier and less costly than the usual plating technic.

Studies of 1,228 blood samples from healthy, infected, and vaccinated swine indicated that mild anemia and an elevation of the leucocyte count were characteristics of the disease, but that neither was a dependable index of infection. Active lymphocytosis was the most striking feature of the blood picture. The opsonocytophagic test, adapted for use in swine, proved helpful in detecting the stage of the disease.

Malignant oedema in swine: Probably due to Clostridium septicum, J. S. Steward (*Vet. Rec., 56 (1944), No. 36, pp. 321–323*).—Malignant edema in swine probably due to *C. septicum* is recorded, apparently for the first time, in Great Britain. What is considered a characteristic clinical picture was observed in nine animals. Swine fever virus infection in the herd appeared to increase susceptibility to the organism; infection in such cases appeared to be via the alimentary tract. Infection in nonvirus-infected herds appeared to follow inoculations or wounds.

Cryptococcus infections in Equidae, S. C. J. Bennett (*Jour. Roy. Army Vet. Corps, 16 (1944), No. 1, pp. 108–118*).—This is a discussion based on 18 yr. of clinical and laboratory experience in the Sudan. It is held that the term "epizootic lymphangitis" should be discarded in favor of the more general term "cryptococcus infection," and that all cryptococci causing suppurative infections in Equidae should continue to be regarded as *C. farciminosus*. In diagnosis, "less attention should be paid to clinical signs and more to the microscopic examination of pus."

Biochemistry in the diagnosis of the diseases of small animals, C. E. HAYDEN (*Cornell Vet., 33 (1943), No. 1, pp. 85–103; also in N. Y. State Vet. Col. Rpt., 1942–43, pp. 63–77*).—This review deals largely with the results of blood studies with dogs and cats. A compilation of data on the composition of dog blood and its significance in pathological conditions is included.

Hematological aids for diagnosis in the dog and cat, L. N. ATKINSON (*North Amer. Vet., 25 (1944), No. 11, pp. 675–679*).—Case histories are presented, with interpretations, as a basis for a discussion of hematological aids which have been found useful in routine practice. It is not thought possible to use the blood count as the sole diagnostic procedure, and hematological work is described as very time consuming.

Fifth annual report of the Regional Poultry Research Laboratory, East Lansing, Michigan, July 1, 1943, to June 30, 1944 (*U. S. Dept. Agr., Bur. Anim. Indus., [1944], pp. 27+, illus. 6*).—A summary is given of the progress of research at the laboratory and cooperating State agricultural experiment stations. This research has been limited primarily to studies related directly or indirectly to the lymphomatosis problem.

The results obtained in breeding over a period of years indicate that resistance to lymphomatosis has been increased in certain lines over that in other lines. Experimental evidence has been obtained to show that transmission of lymphomatosis may occur when healthy birds are brooded and raised in pen contact with infected birds, and that the hatching egg has been incriminated as a possible means of transmitting this disease. Related strains of the causative agent may be used advantageously in studying qualities such as transmission, viability of the agent, and immunology, with the expectation that this information may be applied to studies of lymphomatosis.

The incidence of lymphomatosis among females was greater than among males of the same families. Gonadectomy resulted in an increase in the incidence of the disease. The use of certain sex hormones reduced the incidence of lymphomatosis among the chickens on tests.

There was no correlation between the incidence of lymphomatosis when induced by inoculation and the occurrence of the disease under natural conditions.

Causes of mortality in four successive flocks of broilers at the substation, K. C. SEEGER and A. E. TOMHAVE (*Delaware Sta. Bul. 249 (1944), pp. 23, illus. 2*).—In this study 5,965 birds at the Georgetown Substation were subjected to post-mortem examination from a total of 37,261 chicks started. The average mortality for the 4 commercial-sized experimental flocks was 16 percent (lowest 4.8 and highest 27.9 percent). The periods of highest mortality were the first week and the fifth through the ninth weeks. Coccidiosis, bronchitis, omphalitis, and vitamin A deficiency were the 4 leading causes of death, and collectively were responsible for 75 percent of the mortality. The remaining 25 percent mortality was due to 24 causes, some of which are potentially serious diseases. Pathological changes were found in all but 0.14 percent of the cases by visible means only.

Aspergillosis in fowls, R. P. ASTHANA (*Indian Acad. Sci. Proc., 20 (1944), No. 2, Sect. B, pp. 43–47, illus. 1*).—A serious outbreak encountered in the Central Provinces of India during 1943 is described. *Aspergillus fumigatus* has been isolated from the heart and cutaneous blood, lungs, and other organs of sick birds, eggs, and poultry feed. Mortality was highest in young fowls. Eggs from sick birds hardly ever hatched. White Leghorns were the most resistant of the breeds available.

An electrophoretic study of serum and plasma from normal and leucosis-affected chickens, E. SANDERS, I. F. HUDDLESON, and P. J. SCHAIBLE. (Mich. Expt. Sta. coop. U. S. D. A.). (*Jour. Biol. Chem., 155 (1944), No. 2, pp. 469–481,* *illus. 13*).—A comparative electrophoretic analysis by the moving boundary method was made of the proteins in serum and plasma from normal chickens and from chickens affected with avian leucosis. White Leghorns from 15 to 18 weeks of age were used. A new component, designated the L component, was found in serums from chickens affected with the several forms of leucosis. Although there were no significant differences found in the electrophoretic patterns of serums that would distinguish one type of leucosis from another, it is thought that the presence of the L component in the serum from leucosis-affected chickens may have immunological and diagnostic significance.

The prophylactic effect of sulfadiazine and sulfaguanidine against mosquito-borne Plasmodium gallinaceum infection in the domestic fowl (preliminary report), G. R. COATNEY and W. C. COOPER (*Pub. Health Rpts.* [*U. S.*], *59* (*1944*), *No. 45, pp. 1455–1458*).—Sulfadiazine was given to two series of chicks at a dosage of 1.0 mg. per gram twice daily for 8 days and to one series at a dosage of 0.5 mg. per gram for 4 days, beginning just prior to bites by *Aedes aegypti* mosquitoes infected with *P. gallinaceum.* None of the treated birds developed malaria. When sulfaguanidine was given according to the same plan, 2 of 20 birds receiving the higher dosage and 5 of 12 birds receiving the lower dosage became infected. Of the 34 control birds, 27 developed typical infections. "These data lead us to believe that sulfadiazine has decided prophylactic action against mosquito-borne *P. gallinaceum* infection in the chick; sulfaguanidine at the same oral dosage is considerably less effective."

Possible role of potassium in pullet disease, H. M. SCOTT, E. JUNGHERR, and L. D. MATTERSON. ([Conn.] Storrs Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, *57* (*1944*), *No. 1, pp. 7–10, illus. 2*).—Laboratory records for 1940–43 showed that so-called pullet disease ranked second in pathologic importance among Connecticut poultry diseases, with an average incidence of 22.7 percent and a rate during 1943 of 34.5 percent in 269 lots. In two-thirds of the cases it was characterized by kidney damage similar to visceral gout. A repetition and extension of the work of Correll (E. S. R., 86, p. 79) showed that the "salt effect" resulting from feeding sodium citrate to chicks corresponded to experimental visceral gout, and the protective action of potassium salts against the salt effect was confirmed and shown to hold for simple compounds like potassium chloride or a good agricultural grade of muriate of potash at levels of 1 to 2 percent in the feed. Molasses, due to its potassium content, was found to be protective, which rationalizes the corresponding empirical treatment for pullet disease. In a small-scale experiment on spontaneous pullet disease cases, potassium chloride seemed helpful, which suggests its use during molasses shortage.

Blackhead in turkeys: Notes on its occurrence and its transmission, C. F. SCHLOTTHAUER, F. C. MANN, and H. E. ESSEX (*North Amer. Vet.*, *25* (*1944*), *No. 10, pp. 603–608*).—Following a review of the literature, investigations carried on since 1929 are summarized, including six experiments on transmission of blackhead. These experiments indicated that the causative protozoan organism of blackhead can exist in soil and that it is readily transmitted to susceptible turkeys by contact exposure. The organism was found to be viable after the soil had been pulverized and dried for 15 days at room temperature. Attempts to transmit the disease by confining turkeys with adult chickens in cages having metal or wood floors covered with peat moss or when turkeys were confined in a cage with wire mesh screen floor were unsuccessful. Infection occurred when turkeys were fed from an open feed hopper located in an infected poultry house containing adult chickens. Turkeys having surgically occluded ceca were more resistant to blackhead, but when permitted to range on heavily infected premises losses as great as 33 percent were observed during a single outbreak. It is concluded that turkeys may be raised successfully on infected premises by placing them in an inclosure the floor of which is raised off the ground so that contact with, or soiling of, the ground is prevented.

Erysipelas in turkeys in New York State, E. L. BRUNETT and M. S. HOFSTAD (*Cornell Vet., 33 (1943), No. 1, pp. 105–107; also in N. Y. State Vet. Col. Rpt., 1942–43, pp. 146–147*).—Five outbreaks in New York State are briefly described.

The use of the agglutination test in detecting Salmonella typhimurium carriers in turkey flocks, W. R. HINSHAW and E. MCNEIL. (Univ. Calif.). (*U. S. Livestock Sanit. Assoc. Rpt., 47 (1943), pp. 106–121*).—This paper reports studies on the utilization of the existing knowledge of the antigenic structure of the Salmonellas in an attempt to eradicate *S. typhimurium* from turkey flocks. Results on 151,626 agglutination tests made over a 3-yr. period for four groups of turkey growers are reported. The studies show the necessity of using, as separate tests on each blood sample, two types of antigens at 1–25 as a finding dilution. These are (1) an H or flagellar type and (2) an O or somatic type.

The use of two supplementary specific antigens, one containing the component "i" (*S. kentucky*) in common, and one containing the components 1, 2, 3 (*S. newport*) in common, is found to be a valuable aid in interpretatoin of the H type reactions.

A study of the bacteriological results on reactors autopsied revealed the following percentages of isolations of *S. typhimurium* from various organs: Intestines 80.9, liver 66.7, spleen 66.7, and reproductive organs 16.7.

"Because of the ubiquitous distribution of *S. typhimurium* in animals other than turkeys, it is doubtful if it can be eliminated by testing alone. The results obtained show, however, that the tests described have possibilities as aids in eradicating salmonellosis from a community." The limitations as well as the possibilities of their use are discussed.

Avian salmonellosis: Types of Salmonella isolated and their relation to public health, W. R. HINSHAW, E. MCNEIL, and T. J. TAYLOR. (Univ. Calif.). (*Amer. Jour. Hyg., 40 (1944), No. 3, pp. 264–278*).—During the period 1935–1943, 561 cultures of 23 different antigenic types were isolated from 353 outbreaks in avian species, mainly turkeys in California. This paper gives an account of each type of *Salmonella* studied, with special emphasis on the public health aspect.

S. typhimurium accounted for 60 percent of 291 outbreaks in turkeys and for 35 percent of 43 outbreaks in chickens. *S. bareilly* caused 42 percent of the outbreaks in chickens but only 5 per cent of those in turkeys. Multiple infections were found to exist on the same ranch. On each of two ranches, 6 different types accounted for losses in the period covered by the survey.

AGRICULTURAL ENGINEERING

Domestic fuel possibilities of Maine peat, J. M. TREFETHEN and R. B. BRADFORD (*Maine [Univ.] Technol. Expt. Sta. Paper 46 (1944), pp. 47+, illus. 24*).—This paper is in two parts, of which the first deals with the topics: Present outlook for fuel peat in Maine; nature and occurrence of peat; locations and characteristics of some Maine peat bogs; and quality of Maine peat from selected bogs. From this part of the study it is concluded that in percentage of ash, of substances volatile on ignition, and of fixed carbon as well as in B. t. u. heat value, the heat value of these peats is comparable to that of wood, with which it must compete in this region. There are numerous deposits with sufficient colloidal matter for the manufacture of suitable machine peat fuel, though some deposits are too fibrous in nature to produce a dense fuel.

The second part of the paper, on the operation of fuel peat bogs, takes up machine peat; the machine peat process; selection of the bog; drainage of the bog; capacity of proposed operation; excavating; pulping, or maceration; drying macerated peat; and harvesting. It is here pointed out that a considerable volume of peat is present in Maine, approximating some 150 million tons. Much of this peat is of the fibrous variety, not adapted to the most economical manufacture of machine peat fuel, but there are some deposits of peat, sufficiently decayed and with high colloidal content, that are so adapted. A market for machine peat fuel, if the price can be kept sufficiently low, is recognized. In view of labor conditions and fuel shortages anticipated to continue through the winter of 1944–45 serious consideration of the development of fuel peat is found to be warranted.

AGRICULTURAL ECONOMICS

Agricultural economic reports and publications (*U. S. Dept. Agr., Bur. Agr. Econ., 1944, pp. 52+, illus. 2*).—The work of the Bureau of Agricultural Economics and its organization are described. The periodicals and scheduled reports, with release dates, and the reports and publications by subjects are listed.

[Papers on agricultural economics] (*Jour. Land and Pub. Util. Econ., 20 (1944), No. 3, pp. 194–201, 217–222*).—Included are the following papers: Land Tenure in Brazil, by T. L. Smith (pp. 194–201) (La. State Univ.); and The German TVA, by W. F. Brook (pp. 217–222). The latter is a description of the creation and work of the Rhine Ruhr Authority.

[Investigations in agricultural economics by the North Dakota Station] (*North Dakota Sta. Bimo. Bul., 7 (1944), No. 1, pp. 10–13, 18–25, illus. 2*).—The study of land market activities (pp. 10–12) (coop. U. S. D. A.) is extended through the second quarter of 1944, and tables of farm prices (pp. 12–13) (E. S. R., 92, p. 125) are continued through August 15, 1944. An article, School District Costs in Western North Dakota, by M. H. Taylor (pp. 18–25), discusses the operation of districts, number and enrollment of schools, variations in taxable wealth and tax rates, receipts, expenditures, and indebtedness of the districts, and makes suggestions for reorganization.

[Investigations in agricultural economics by the Ohio Station] (*Ohio Sta. Bimo. Bul. 231 (1944), pp. 274–276, 277*).—An article by C. W. Hauck analyzes the cost of producing apples in 1943 as reported by 136 growers with 6,114 acres of bearing trees. The table of index numbers of production, prices, and income by J. I. Falconer is brought down through August 1944.

The Agricultural Situation, [November 1944] (*U. S. Dept. Agr., Bur. Agr. Econ., Agr. Situation, 28 (1944), No. 11, pp. 31, illus. 3*).—This annual outlook issue includes brief summaries on different economic conditions and commodities prepared by staff members of the Bureau of Agricultural Economics, and is based chiefly upon the materials used at the Twenty-second Annual Outlook Conference held in Washington, November 13–18, 1944.

1945 Agricultural outlook charts (*U. S. Dept. Agr., Bur. Agr. Econ., 1944, pp. 100+, illus. 103*).—"The charts in this book have been selected as those most likely to be of use to extension workers in presenting the basic facts regarding the major crop and livestock industries and the food situation. They are intended as a supplement to the mimeographed reports on the farm outlook for 1945."

The impact of the war on the financial structure of agriculture, A. S. Tostlebe, D. C. Horton, R. J. Burroughs, H. C. Larsen, L. A. Jones, A. R. Johnson, et al. (*U. S. Dept. Agr., Bur. Agr. Econ., 1944, pp. 191+, illus. 35*).—Part 1, Changes in the Financial Structure of Agriculture, 1940–44, discusses the balance sheet, the income statement, and the changes in the real estate, non-real estate physical inventories, intangibles, farm real estate and non-real estate debt, proprietary equities, and economic forces of World War II compared with World War I. Part 2, Financial Structure of Agriculture in the Post-war Period, discusses the immediate and later post-war developments affecting the financial structure.

Farmers in the war (*Washington: [U. S.] Off. Price Admin., 1944, pp. 76+, illus. 63*).—Tables and charts compare the prices of commodities sold and purchased by farmers during Wars I and II, prices of farm products and industrial goods, farm operating income, savings, farm prices after War I, and similar material.

Useful records for family farms, S. W. MENDUM (*U. S. Dept. Agr., Farmers' Bul. 1962 (1944), pp. 29+*).—Why records should be kept and the kinds of records needed are described. Records of property or inventory; receipts and expenses; production, performance, and incidental matters; household accounts; and the summarization of results and depreciation details are discussed. This supersedes Farmers' Bulletins 511, 572, and 1182 (E. S. R., 28, p. 191; 30, p. 793; 44, p. 593).

Relation of total income on farms to price index, F. B. HEADLEY and M. L. HARTLEY (*Farm Mangt. Bul. [Nevada Sta.], 5 (1944), No. 1, pp. 7+, illus. 3*).—The abstract (E. S. R., 91, p. 758) should read as follows: "The following relations, indicated by regression equations, were found for the period 1929–43 between (A) gross farm income of four cooperating Nevada farmers with the Nevada farm price index, $y = -29.4 + 1.02x$; (B) U. S. D. A. Bureau of Agricultural Economics gross farm income for Nevada with the Nevada farm price index, $y = -27.7 + 1.07x$ and (C) U. S. gross farm income index with the U. S. farm price index, $y = -34.5 + 1.29x$."

Getting started in farming, M. R. COOPER (*U. S. Dept. Agr., Farmers' Bul. 1961 (1944), pp. 33+, illus. 16*).—A bulletin for persons knowing little or nothing about farming and those with farming experience but desirous of changing location. It gives information to assist in selecting a location, selecting a farm, and getting started in farming. It supersedes Farmers' Bulletin 1088 (E. S. R., 43, p. 291).

The Cumberland Plateau in Tennessee, F. N. MASTERS and C. E. ALLRED (*Tennessee Sta. Bul. 192 (1944), pp. 32, illus. 17*).—This bulletin, planned for prospective settlers, includes information as to physical features, soils, climate, industries, transportation, markets, taxes, credit facilities, agriculture, population, etc. A list of 55 literature citations is included.

Labor, materials, and cost of clearing land on Cumberland Plateau, H. J. BONSER, C. E. ALLRED, and C. C. MANTLE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 177 (1944), pp. 39+, illus. 31*).—Information from 97 tracts handled in different ways showed the following averages on an acre basis: Estimated value of products, $36.81; cost of clearing, $24.41; and labor requirements to the stump stage, 123.1 hr. plus 2.6 mule hours. The average hours required for different operations were: Girdling, 11; felling, 47.2; brush removal, 48.9; destroying tops, 16.6; pulling stumps, 40.9; and destroying stumps, 9.0.

Former use of land now in Douglas Reservoir, H. J. BONSER (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 176 (1944), pp. 39+, illus. 11*).—Using A. A. A. compliance records for 421 farms embracing 92 percent of the lands lying wholly or partially in the reservoir, the 1939 use of lands below pool level and the land remaining of tracts directly affected are described.

Combinations of enterprises on plantations in the lower Arkansas River Delta, J. W. WHITE. (Coop. U. S. D. A.). (*Arkansas Sta. Bul. 449 (1944), pp. 75, illus. 5*).—The study is based on a survey made in 1930 of 38 plantations, a follow-up survey in 1941 of 20 of the same plantations, and data on crop and livestock enterprises for a random sample of 443 Delta farms in Jefferson County obtained by the A. A. A. and the Arkansas Agricultural Extension Service. The changes in the enterprises from 1929 to 1940, the production requirements, yields, prices, etc., are discussed. Using the findings as to production requirements, yields, costs, prices, etc., budgets of estimated costs, monthly labor requirements, and returns to operators and sharecroppers are set up for an approximate 1,125-acre plantation with approximately 794 acres of cropland, 221 acres of woodland pasture, 68 acres of wasteland, and 41 acres of farmstead, roads, and ditches. The budgets cover three types of organization built around cotton as the principal source of income (285 acres) and the following supplementary sources: (1) Production of feeder calves and feed crops, (2) soybeans and feed crops, and (3) soybeans, feed crops, and sufficient beef cattle to utilize noncrop lands and pastures. The returns are computed on the basis of assumed relative prices and 1942 prices.

From 1929 to 1940 the cotton acreage per 100 acres of cropland was reduced approximately 50 percent. The chief increases in other crops were: Lespedeza 12 acres, and corn and small grains 6.5 acres, per 100 acres of cropland. Work stock decreased slightly and all other livestock, especially beef cattle, increased. With assumed relative prices the estimated net returns per family for operator and per sharecropper were: With feeder calves and feed crops, —$2,593 and $244; soybeans and feed crops, $1,932 and $230; and soybeans, feed crops, and beef cattle to utilize pastures, $1,617 and $234.

Returns from poultry farming in Massachusetts in 1943, C. R. Creek. (Coop. U. S. D. A.). (*Massachusetts Sta., 1944, FM-17, pp. 27+, illus. 4*).—Analysis is made of 24 poultry account books distributed by the Extension Service including analysis of farm business and analysis by size and type of business. Flock maintenance is discussed and comparison made of the farm returns, 1939–43.

How some poultrymen made a profit in 1943, C. R. Creek (*Massachusetts Sta., 1944, FM-18, pp. 14*).—The operations, expenses, returns, etc., of several farms are described.

Efficiency as applied to cotton ginning business, W. E. Paulson (*Texas Sta. Bul. 654 (1944), pp. 39, illus. 11*).—Efficiency as discussed in this bulletin is confined to the ginning business in Texas. Cost as a measure of efficiency; standards of ginning business—gin income, cost of ginning, and volume of business (E. S. R., 87, p. 132); the profit experiences of different groups of gins; the standard costs of 1927–28 and 1937–38; profit as an index of business efficiency; size of crop, number of gins, and returns on investment; variations in ginning costs from standard costs; volume of ginning and efficient use of capital, etc., are discussed. Charts show the effect of volumes of ginnings greater and less than standard volume; relation between fixed and variable cost per bale and total cost to volume of ginning; relations among size of crop, number of operating gins, and average profit on gin investment; relations among volume of ginning, gin income per bale, and number of years required to finance a plant from profits; relation of volume ginned to cost per bale as influenced by cost efficiencies; influence of volume of ginning on investment, capital requirement, and profits per bale; and relation of cost per bale and returns on gin investment to cost of ginning, gin income, and volume of ginning. Equations for estimating total standard costs and items of costs for different areas of the State are given in the appendixes.

Marketing South Carolina sweetpotatoes, W. T. Ferrier (*South Carolina Sta. Bul. 352 (1944), pp. 30, illus. 2*).—Information is assembled from Federal, State, and private sources, from questionnaires on consumers' preferences, marketing practices, and problems circulated by the Southeastern Chain Store Council and the author; and on production and marketing practices through interviews with growers, former members of the South Carolina Sweetpotato Growers Association, the Extension Service, and the experiment station staff. The production possibilities for food, feed, and industrial uses, the varieties and supply areas, factors affecting production and marketability, consumers' preferences, and methods of improving marketability are discussed.

Peach marketing practices in the Nashville-Highland district of Arkansas in 1940, J. W. White and O. T. Osgood (*Arkansas Sta. Bul. 452 (1944), pp. 32, *illus. 3*).—Data for the 1940 season on production, yields, grades, market defects and their causes, preparation for market, sales, marketing methods and practices, truck transportation, and factors associated with prices, collected from 63 farms and regarding 100 truckloads of peaches, are analyzed and discussed.

Butterfat differentials used in paying producers for market milk, L. SPENCER and S. JOHNSON. (Cornell Univ.). (*Amer. Milk Rev., 6 (1944), No. 10, pp. 302–308*).—The differentials used in various large markets of the United States are discussed.

An inventory of farmers' cooperatives operating in Pennsylvania in 1943, J. K. STERN (*Pennsylvania Sta., Jour. Ser. Paper 1254 (1944), pp. 41+, illus. 21*).—The early history and development of cooperatives in the State, the cooperatives for marketing different kinds of commodities, purchasing cooperatives, and the Pennsylvania Association of Cooperative Organizations are described with data as to the location, business, etc.

Cooperative purchasing of seed in relation to crop production, T. E. HALL (*U. S. Dept. Agr., Farm Credit Admin., Misc. Rpt. 74 (1944), pp. 36+, illus. 13*).—The development, present status, and operations of local and regional cooperatives for the purchase of seed are discussed.

Delivery conservation practices of cooperative oil associations affiliated with the Farmers Union Central Exchange, J. W. MATHER (*U. S. Dept. Agr., Farm Credit Admin., Misc. Rpt. 77 (1944), pp. 39+, illus. 3*).—A study was made in the summer of 1943 of 21 representative local cooperative oil associations, located in 5 States and associated with the Farmers Union Central Exchange, St. Paul, Minn., by personal visits and mail. The performance records of trucks and the factors affecting delivery conservation and efficiency are analyzed, and the aids in developing delivery efficiency are discussed. Suggested delivery efficiency record forms are included.

Delivery records (31 trucks) showed the gallons delivered per mile driven ranged from 5.9 to 20.6. Operating costs (6 trucks) averaged 0.5 ct. per gallon and 5 ct. per mile. Total delivery costs ranged from 1 to 1.5 ct. per gallon and 12 to 15 ct. per mile. Records for a limited number of tank trucks showed a 25 percent improvement during the war in terms of gallons delivered per mile driven, the increase being as high as 50 percent in two cases. Trucks with over 600-gal. tanks delivered about 12.5 percent more gasoline per mile than those with 600-gal. tanks. Redistribution of barrels to farmers, increase of time on "on order" deliveries, standing orders, larger deliveries, lengthening intervals between regular deliveries on scheduled routes, discontinuance of special deliveries, solicitation of business, and collections with the trucks were methods found important in increasing delivery efficiency.

Foreign Agriculture, [December 1944] (*U. S. Dept. Agr., Foreign Agr., 8 (1944), No. 12, pp. 269–284*).—An article, New Zealand's Agricultural-Marketing Policies, by M. Wright (pp. 270–281), describes the farm resources, production, markets, the activities of export-control boards, the Empire relations and agricultural policy, guaranteed prices, internal marketing control of different products, the bulk-purchase agreements, and considerations affecting future policy. The United Kingdom Wartime Policy and Post-war Program for Milk is described by D. D. Jones (pp. 282–284).

International trade increases demand for farm products (*U. S. Dept. Agr., 1944, AIS-1, pp. 16, illus. 10*).—A popular discussion of the need of imports, effect of foreign trade on living level, effect of depression and self-sufficiency on international trade, how farmers gain from export of industrial products, lend-lease, effects of tariffs, trade agreements, and post-war planning for world trade and peace.

Crops and Markets, [July and October 1944] (*U. S. Dept. Agr., Crops and Markets, 21 (1944), Nos. 3, pp. 113–156, illus. 2; 4, pp. 157–192, illus. 2*).—Included in both publications are tables and charts of the usual types on yields and production of different crops, stock of grains on farms, farm employment and wage rates, hog-corn ratios, prices received and paid by farmers, and market reports for cotton, dairy and poultry products, feed, grains, livestock, and livestock products. No. 4 also includes data on sales and use of fertilizers for cotton and on egg, wool, and milk production.

Farm production, farm disposition, and value of hay, 1909–41, by States, C. G. CARPENTER ET AL. (*U. S. Dept. Agr., Bur. Agr. Econ., Crop Rptg. Bd., 1944, September, pp. 50+, illus. 1*).—Tables show by year for the United States and the several States the production of tame and wild hay, the disposition, the season average price per ton, and the value of production and sales.

Cotton acreage, yield, and production, 1942 and 1943, by counties (*U. S. Dept. Agr., Bur. Agr. Econ., Crop Rptg. Bd., 1944, pp. 29+*).

Use of machinery and horses on Maine farms keeping dairy cows, G. F. Dow (*Maine Sta. Bul. 429 (1944), pp. 41–79+, illus. 3*).—The greater part of the data was obtained in a study of about 500 farms in five general dairying areas of the State in the summer of 1943. Other information was drawn from previous studies and the 1940 Census. The number of farms having different kinds of equipment, the age of the equipment, and the needs for new equipment; the use and costs of operating automobiles, trucks, tractors, and of keeping and using horses; the use of electricity; the investment in machinery; the comparative efficiency of different kinds of tractive power; the methods of handling hay; and the effects of use of milking machines, barn equipment, etc., on costs and labor requirements are analyzed and discussed.

Maryland farm statistics, C. E. BURKHEAD, D. B. WILSON, and A. B. HAMILTON. (Coop. U. S. D. A.). (*Maryland Sta. Bul. X3 (1944), pp. 110+, illus. 7*).—Statistics from the earliest dates available are included on acreages (or numbers), production, monthly prices, and value of different crops and kinds of livestock, real estate, incomes, wage rates, etc., and also on planting and harvesting seasons, and distribution of acreages of crops, livestock, and poultry by counties.

RURAL SOCIOLOGY

The urban status of rural migrants, H. W. BEERS and C. HEFLIN. (Univ. Ky.). (*Social Forces, 23 (1944), No. 1, pp. 32–37*).—The authors found that rural migrants in Lexington, Ky., constitute large proportions of the population at each economic level, although their representation is greatest at the lowest level. With education and income somewhat below that of their urban-reared neighbors, they report general approval of their community and especially of its institutions. They report a decrease in some forms of social participation, they are completely convinced that high school education is important, and they appreciate the superior standards of living in Lexington compared with the rural districts from which they came.

Virginia rural organization trends and needs, W. E. GARNETT (*Virginia Sta., Rural Sociol. Rpt. 30 (1944), pp. 13+, illus. 2*).—This report of a committee appointed to revise the program of the Virginia Farm Bureau is a synopsis of several research projects upon community trends and development. Included are suggestions for desirable voluntary rural organization activities and a discussion of unmet needs and how to meet them.

Forward steps in Virginia rural health and medical care, W. E. GARNETT (*Virginia Sta., Rural Sociol. Rpt. 29 (1944), pp. 12+*).—This is a report, with recommendations, of the Sponsoring-Advisory Committee Meeting on the Virginia Rural Health and Medical Care Study, held at Lynchburg June 2–3, 1944, and of the executive committee held July 7. Background findings from other studies are presented in four appendixes.

Prepayment medical-care plans for low-income farmers in Ohio, R. L. McNamara and A. R. Mangus. (Coop. U. S. D. A.). (*Ohio Sta. Bul. 653 (1944), pp. 29+, illus. 1*).—In this study of prepayment medical care, planned in cooperation with the Farm Security Administration, it was found that under FSA plans females received a greater volume of physicians' services than did males, that adults received more than young people and children, and that tenants received a larger share of physicians' services than did owners. Persons of low economic status received more of such services than those more advantaged. Members of small-sized households received more of such services than those who were members of larger-sized households. Persons with little schooling received more services than those more advanced, and medical service was greatest in the winter months and least in the summer. More than one-half of a physician's contacts with patients were for treatment of respiratory and digestive disorders and diseases and conditions of the reproductive and urinary organs. Farm Security Administration plans were subject to a highly selective turn-over resulting in a situation wherein participants consist of a disproportionately large number of people requiring an extensive amount of medical care. FSA medical service met only a part of the total need for medical care. The volume of medical services received by participating families was in excess of that generally received by farm families, but still far below adequacy as defined by competent authorities. It is concluded that regardless of a proper distribution of risks among participants, the low-income FSA families will be unable to pay the family costs of an adequate health insurance program.

FOODS—HUMAN NUTRITION

Estimation of food value by chemical methods of another series of edibles consumed in Bihar, K. Mitra and H. C. Mittra (*Indian Jour. Med. Res., 30 (1942), No. 2, pp. 299–307*).—In continuation of investigations already reported (E. S. R., 87, p. 589), the results of analysis of a further series of 80 items are presented. Calcium, phosphorus, and proximate constituents are reported for 4 grain foods; 6 flesh foods; 22 fruits; 44 vegetables, including leafy types, roots and tubers, and miscellaneous vegetables; and buffalo, goat, and cow's milk, and buttermilk (buffalo). Hindi or local names, English names (where available), and Latin names are given.

The determination by chemical methods of the food values of yet another batch of edibles, K. Mitra and H. C. Mittra (*Indian Jour. Med. Res., 31 (1943), No. 1, pp. 41–43*).—Data obtained in the present investigations are reported for proximate constituents and Ca and P contents of 50 foods utilized in India. These include 2 kinds of grain foods; 14 of flesh foods—including several kinds of turtle meat, prawn, crab, lobster, meat of narrow-snouted crocodile, fish roe, and venison; 9 of fruits; 10 of leafy vegetables; 9 of root vegetables, and 6 of other vegetables. The foods are designated by Hindi or other local names, English names (where available), and Latin names.

A note on the presence of calcium oxalate in the maya fruit, C. F. Asenjo, J. A. Goyco, and M. del C. Fernández. (Puerto Rico Expt. Sta. et al.). (*Jour. Amer. Pharm. Assoc., Sci. Ed., 33 (1944), No. 10, pp. 344–345, illus. 1*).—The edible portion (pulp) of the maya fruit (*Bromelia pinguin* L.) was found upon microscopic examination to contain a large number of calcium oxalate crystals averaging about 108μ in length and 5μ in cross section. Whole maya fruit, whole pineapple, and the edible part of wild native (Puerto Rican) taro, all in the fresh state, averaged, respectively, 0.0838, 0.0089, and 0.1260 percent free and combined oxalic acid as $CaC_2O_4.H_2O$.

Nutritive value of soybeans, G. M. KINSMAN. (Univ. Ill.). (*Soybean Digest, 4 (1944), No. 12, pp. 9–10, 15*).—A brief review, with bibliography of 27 references.

Some problems in using soybeans as food, J. I. SIMPSON. (Univ. Ill.). (*Soybean Digest, 4 (1944), No. 11, pp. 43–44*).—This is a brief discussion of the utilization of vegetable soybeans and soybean flours and meals in the diet.

Nutritional value of bread containing soya flour and milk solids, R. S. HARRIS, M. CLARK, and E. E. LOCKHART (*Arch. Biochem., 4 (1944), No. 2, pp. 243–247*).—The eight breads prepared by a commercial bakery were kept constant with respect to the quantities of white flour, water, yeast, Arkady, salt, lard, sugar, and malt and were all enriched with vitamins and minerals at levels corresponding to existing flour standards. The skim milk solids content in the several breads varied from 0–6 percent and the full-fat soya flour content from 0–5 percent of the weight of the flour in the bread formula. To compare these breads with regard to the nutritive quality of their proteins, they were fed at a 10–percent protein (1.8–percent nitrogen) level to eight groups of rats receiving an otherwise similar complete diet. Weight gains of these animals (per 100 gm. of food or per gram nitrogen consumed) over an 8–week period showed that the bread containing 3 percent soya flour and 3 percent skim milk solids produced the best growth, even superior to that of animals receiving breads made with 6 percent skim milk solids or 5 percent soya flour. A bread containing 2.3 percent skim milk solids and 3 percent of the soya flour was superior to a bread containing 6 percent milk solids not fat. The superior values of blended proteins were also shown in the case of bread containing 1.5 percent skim milk solids and 2.5 percent soya flour as compared with one containing 4 percent skim milk solids or 3 percent soya flour. The bread containing neither soya flour nor skim milk solids showed the poorest growth of all.

Some factors affecting the behavior of Cheddar cheese in cooking, C. PERSONIUS, E. BOARDMAN, and A. R. AUSHERMAN. (Wis. Expt. Sta.). (*Food Res., 9 (1944), No. 4, pp. 304–311, illus. 1*).—Experimentally produced Cheddar cheese, prepared from pasteurized milk, and other samples of known type and approximate age obtained on the retail market, were used in this study to determine the effects on cooking behavior of the cheese due to its composition and degree of ripening, and to the intensity and length of heat treatment and the reaction of the dispersing medium. Six lots studied over a 12–mo. period of ripening showed a progressive increase in the amount of the total protein that was soluble in acetate buffer solutions, pH 4.6, containing 1 percent and 5 percent NaCl. In four lots of normal fat content there was a progressive improvement in cooking quality over 12 mo. of ripening.

"This improvement was more rapid in a high-moisture cheese. In general, cheese ripened in hermetically sealed cans showed a more rapid improvement in cooking quality than part of the same curd ripened in a daisy. There was no direct correlation between the percentage of the total protein that was soluble and the observed cooking quality. However, the cooking quality improved and the amount of soluble protein increased with the length of the ripening period. Low-fat cheeses were conspicuously poor in cooking quality. Relatively high temperatures and long periods of heating tended to cause greater separation of fat from a cheese; matting, stringing, and toughening of the cheese mass were also increased.

"The acidity and the ion content of the liquid with which a cheese is combined apparently affect the blending qualities and the tendency of the mixture to mat or string on heating. Between pH 5.2 and 5.6 the greatest tendency for matting and stringing was observed. At acidities between pH 4.0 and pH 4.7 to 5.0 the cheese separated from the liquid with which it was combined as hard, curdlike particles, while within the range pH 5.8 to 8.0 appreciable dispersion was observed. It is possible that the calcium-removing property of the phosphates in the buffer solutions of pH 5.8 and above played a major part in increasing the dispersion of the cheese."

A microscopic study of the behavior of fats in cake batters, G. T. CARLIN (*Cereal Chem., 21 (1944), No. 3, pp. 189–199, illus. 6*).—Batters of the pound cake and white layer cake type were used, being maintained at a temperature of 75° F., except as heated in baking. Microscopic observations (recorded by means of photomicrographs) were made on minute portions of the batter pressed out by a cover glass on a glass slide. The fat was colored with fat-soluble dyes to facilitate following its behavior prior to and during baking. Changes during baking were followed in batters cooked or baked on the slides by means of a specially devised heating stage. Batters thus baked were compared with similar batters removed from cake layers during the regular process of baking. At the point at which batters became baked the characteristic birefringence of the starch granules under polarized light disappeared. This loss of birefringence when a film of the batter was baked on the slide was confirmed with cakes baked in a normal manner. The observations indicated further that layer and pound cake batters are apparently suspensions of air bubbles in fat distributed in a medium of flour and liquid.

"Little, if any, liquid appears to be emulsified in the fat. Soluble ingredients such as salt and sugar are dissolved by the water of the batter. The air spaces in layer and pound cake batters are invariably surrounded by fat. During baking, the fat quickly melts and releases its suspended air to the flour-water medium. Gas produced by baking powder finds its way into the air spaces already existing in the batter. . . . There is a movement of air spaces at all times during the baking process. This movement appears to follow a definite convection pattern until the end of the baking process is neared. At this stage the movement becomes violent and without direction. The use of monoglyceride emulsifying agents produces a finer dispersion of fat throughout the cake batter."

Effect of flavor on nutritive value of fats, R. K. BOUTWELL, R. P. GEYER, C. A. ELVEHJEM, and E. B. HART. (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc., 55 (1944), No. 3, pp. 153–155*).—Experiments are reported refuting the claim of Deuel et al. (E. S. R., 89, p. 759) that the superiority of butterfat over corn oil or other vegetable fats in growth-promoting properties for young rats receiving lactose as a sole carbohydrate is due to a greater food consumption because of the butter flavor diacetyl.

Four groups of 12 weanling rats each were followed for 6 weeks on diets (fed ad libitum) in which lactose was the sole carbohydrate and the fat consisted of butterfat, corn oil, butterfat from which diacetyl had been removed chromatographically, and corn oil to which 0.0005 percent diacetyl had been added. The average gains on the four rations were 145, 110, 152, and 124 gm., respectively. The animals receiving corn oil were decidedly inferior in appearance to those receiving butterfat. Two control groups receiving dextrose as carbohydrate, with butterfat and corn oil as fats, grew at approximately the same rate, gaining 186 and 183 gm., respectively, and were of normal appearance at the end of the experiment.

Experiments on garlic and onion extracts, W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 10, pp. 305, 313*).—This brief report, based on preliminary tests, suggests that for commercial trial the garlic extract be made by treating 100 parts of ground garlic with 120 parts of 100-grain vinegar, 25 parts of salt, and 180 parts of water (all measurements by weight), allowing the mix to stand overnight, then pressing, straining, and bottling. Extraction with brine or by treatment with water, salt, and Pectinol yielded products which darkened rapidly. Onion extracts were also prepared, but these were not considered so desirable as onion powder prepared by hammer milling and sieving the dehydrated onions.

Microbiological problems in the preservation of meats, L. B. Jensen (*Bact. Rev., 8 (1944), No. 3, pp. 161–188*).—This review, with 117 reference citations, discusses: (1) Action of certain bacteria on myohemoglobin and nitric-oxide derivatives formed in cured meats, (2) ante-mortem and post-mortem changes of tissues of food animals, (3) action of micro-organisms on fats, (4) effect of nitrates and nitrites on bacteria in cured meats, (5) action of NaCl on bacteria, and (6) some recent developments in meat technology.

Curing important to southern lockers, D. E. Brady. (N. C. State Col.). (*Quick Frozen Foods, 6 (1944), Nos. 12, p. 53, illus. 3; 13, p. 57, illus. 1*).—A meat-curing service is recommended for operation along with meat-freezing service by southern locker plants, in order that the meat supply of southern farmers may be extended and varied, with assurance against curing loss.

Meat dehydration: A report of research work for its commercial development (*U. S. Dept. Agr. Cir. 706 (1944), pp. 46+, illus. 7*).—On the basis of boned, trimmed, fresh meat, dehydration is estimated to save approximately 60–70 percent in weight. Reduction in volume, when the dehydrated product is properly compressed, is from 65 to 73 percent, approximately.

Of the various processes studied, the vacuum rotary seemed likely to have the most advantages. It involves rotary agitation of the meat in a steam-jacketed cylinder under reduced pressure. Meat processed by this method had good rehydration capacity, thiamine retention, palatability, and keeping quality, and had other desirable characteristics. The vacuum rotary process, moveover, is simple, combining both precooking and drying in one machine. Some of the other seven processes examined were superior, however, with respect to rate of drying, continuity of operation, palatability of freshly dehydrated product, or in other points. Control over processing temperatures and of air oxidation was found to be important to successful dehydration. Dehydrated raw meat, as removed from the drier, appeared to be generally a better product than dehydrated cooked meat but presented a problem in keeping quality requiring further study. High stability in dehydrated meat (resistance to the development of rancidity) was found to be associated with high palatability. Tests for oxidation and rancidity showed the importance of using, for dehydration, fresh meat that had not been aged. Meat may be fully acceptable for table use and yet be unsuitable for dehydration because of previous action by enzymes or exposure to air oxidation. The use of small quantities of gum guaiac as an antioxidant improved the keeping quality of dehydrated meat. Conditions of processing, packaging, and storing that reduce exposure to air helped in obtaining good keeping quality.

Metal cans were found the best containers for dehydrated meats and kept them in satisfactory condition for long periods. Besides affording good protection against rough handling and contamination, such containers exclude air and otherwise preserve the palatability of the meat better than others, especially at nonrefrigerating temperatures. The most satisfactory substitute for cans was the envelope-type, lead-foil bag. Some paper and other nonmetallic containers, fairly satisfactory under favorable storage conditions, failed when exposed to high humidity and frequent temperature changes. Dehydrated meats canned by the vacuum-pack process retained their palatability slightly better than those canned in an atmosphere of nitrogen. Nitrogen-pack products were slightly better than air-pack meat. Low storage temperatures aided in retaining palatability of canned dehydrated meats.

Dehydration of meat scrapples, B. C. CARL, B. M. WATTS, and A. F. MORGAN. (Univ. Calif.). (*Food Res., 9 (1944), No. 4, pp. 319–327*).—A scrapple that dehydrated successfully and that did not turn rancid readily was made from ground lean pork 1 lb., water 1 cup, polenta-grind corn meal ½ cup, salt 1 teaspoon, and pepper ⅛ teaspoon. In developing this formula it was found (1) that the fat content of the fresh pork used should not be over 20 percent, preferably 12 to 18 percent, corresponding to a fat content in the dehydrated scrapple of about 30 percent; (2) that the amount of water used should be the minimum to hydrate the corn meal; (3) that the corn meal should be coarse enough to allow adequate rehydration of the scrapple but not so coarse as to cause excessive tenderness; and (4) that only salt and pepper should be used as seasoning, since other seasonings sometimes imparted undesirable flavor. In making the scrapple the water was added to the cooked meat and brought to a boil and the corn meal and seasoning were added gradually with stirring. When the scrapple began to thicken it was placed in a double boiler, steamed for 30 min., and then moulded. Slices about 3/16-in. thick were spread on trays and dehydrated at 155° F. for 5–6 hr.

"Scrapple may be eaten in the dehydrated form or reconstituted into patties, meat loaf, or creamed preparations. It can be compressed to about 60 percent of its original volume to save storage and shipping space. When compressed it contains about 5 calories per cubic centimeter and has a density of about 1 gm. per cubic centimeter. An average scrapple had a moisture content of 4 percent, a protein content of 37 percent, and a fat content of 28 percent. Palatability tests showed that dehydrated scrapple is much preferred to dehydrated ground pork, either raw or steamed. Other cereals, particularly barley, cracked wheat, and chipped rye, may be substituted for part of the corn meal to improve the flavor. Other meats may also be substituted for pork, beef being particularly successful."

Observations on dehydraters, E. BALOG and W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 11, pp. 329–331, 346*).—Data obtained on the moisture content of carrots, potatoes, and cabbage taken from different locations throughout commercially operated tunnel dehydrators showed that moisture evaporated very rapidly from the fresh product in the early stages, but that the final stages of drying were slow. Since the moist product in the initial stages of drying can withstand higher temperatures than the product at the final stages, it is suggested that the drying be started with high temperature and high air velocity and that the partially dried product be placed in a second tunnel or other drier to be finished in air at lower temperature and velocity than in the primary tunnel. It is also suggested that trays of the partially dried product be doubled up or trebled up in some cases so that one secondary tunnel may serve two or three primary tunnels.

Some factors influencing quality of dehydrated, canned, and frozen green beans, D. C. ALDERMAN and B. NEWCOMBE. (Mich. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 12, pp. 365–368, illus. 3*).—"Green beans of the Stringless Greenpod variety were cut crosswise in pieces 1¼ in. and ¼ in. long, lengthwise in fourths, and processed by dehydration, canning, and freezing. After processing, they were divided into four lots. The first was reconstituted and tested for palatability and quality immediately, and the other three lots were stored and tested after 1, 3, and 6 months' time. The judges scored the product as to desirability of color, consistency, flavor, and rehydration, by indicating whether each of these quality factors was very good, good, fair, or poor. The experiment, which was replicated four times, was set up on a split plot design and data reduced by applying analysis of variance.

"The results obtained from this experiment show clearly that dehydrated shredded green beans are not only superior to canned beans, but equal to those frozen. Here, then, may be found another market for green beans. The dehydrated shredded beans were significantly superior to the dehydrated beans cut crosswise. The inability of these long-cut and short-cut beans to rehydrate was largely responsible for their poor quality scores.

"The ratings accorded color and flavor of the canned beans were inferior to those of the dried shreds and frozen beans. All of the beans, dehydrated, canned, and frozen, decreased significantly in quality after 6 months' storage."

Some factors affecting the variability of dehydrated carrots, L. K. MANN and E. WEIER. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 10, pp. 309–311, 317, illus. 1*).—Variations in the amount and distribution of starch and carotene in the raw carrot and changes occurring in these constituents during dehydration were followed in histological studies of carrot sections. Starch, present as individual grains, was not uniformly distributed in the root, but when present was most often to be found near the boundary between the central core and the outer portion. When the raw carrot was blanched preliminary to dehydration the starch was gelatinized. If the carrot dice were heated to blanching temperature of 170° F. or higher within 30–60 sec. the gelatinized starch appeared as an amorphous mass within the cells. If the carrot dice were heated more slowly to the same blanching temperature, the starch swelled and gelatinized and then became converted to dextrin. In carrot dice dehydrated without blanching, the starch remained in the form of grains if the drying temperature was kept below 120° until about half of the moisture was lost.

Carotene distribution in the raw carrot was exceedingly variable. Because of this variability in distribution the external color of the carrot was not a good index of carotene content of the whole carrot, at least when small differences were concerned. Moreover, the color of the carrot was found to be modified by the presence of air in the tissue. Carotene in the dehydrated tissue often appeared in small yellow droplets of carotene in oil; occasionally the pigment remained in crystallike bodies after dehydration; and in some cases there was evidence of carotene breakdown.

Effect of syrup treatment on compressing of dehydrated carrots and cabbage, B. J. CYTRON, E. BALOG, and W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 11, pp. 338–339*).—"The compressibility of dehydrated carrots at relatively low temperatures (100°–120° F). and adhesion of the compressed products were greatly improved by dipping blanched carrots in 50° Brix dextrose solution and blanched cabbage in 30° Brix dextrose solution before dehydration. The dried products were not too sweet in flavor. Yield was increased. Keeping quality is under study and will be reported later."

Sulphite retards deterioration of dehydrated cabbage shreds, G. MACKINNEY and L. B. HOWARD. (Univ. Calif. and U. S. D. A.). (*Food Indus., 16 (1944), No. 5, pp. 75–76, 126–129, illus. 1*).—This report, based on information from laboratory tests, pilot-plant data, and industrial tests, discusses the adjustments necessary in individual plant operations to solve the problem of producing sulfited dehydrated cabbage under Army contract. Recent Quartermaster Corps specifications for dehydrated cabbage include a requirement for sulfiting, prior to dehydration, with limits of 750 to 1,500 p. p. m. of sulfur dioxide in the finished product.

Variety, place of production, and stage of maturity as factors in determining suitability for dehydration in white potatoes, J. S. CALDWELL, C. W. CULPEPPER, and F. J. STEVENSON. (U. S. D. A.). (*Canner, 99 (1944), Nos. 1, pp. 26–34; 2, pp. 16, 18, 24–30*).—This study, carried out with early-crop potatoes from the more important southern potato-producing districts, is in extension of earlier work using potatoes from the more important northern potato-producing districts

(E. S. R., 90, p. 272). The material employed was supplied by cooperators in the National Potato Breeding Project in Texas, Florida, Louisiana, South Carolina, Virginia, California, Maryland, and New Jersey. There were 34 lots of material, 27 dug at commercial-harvest stage when the vines were still green, and 7 dug 10 days to 2 weeks later when the vines had become dead and dry. As the lots of potatoes were dug they were shipped by express or truck to Beltsville, Md., where they were dehydrated within 2 to 3 days of receipt by methods employed in the earlier study. Dry yield, as percentage of prepared strips placed in the dehydrator, varied from 15.1-25.3 percent, with the majority of the samples falling within the range of 17–20 percent and with the delayed-harvest potatoes showing larger dry yields than the physiologically immature, commercial-harvest samples. The tendency to dark discoloration during preparation for drying was most pronounced and difficult to control in the immature potatoes; imperfect control was attained by dipping the potatoes in salt solution prior to blanching, but dipping into a dilute sulfur dioxide solution very satisfactorily prevented the darkening. The distinct yellowing observed in all lots within 30–60 min. after being placed in the dehydrator was attributed to the presence of carotene in the potatoes.

When cooked and prepared as riced potato, none of the samples was of the highest quality; 13 ranked good to very good, the remaining 21 from very good through fair or acceptabie to poor. The final quality grade of the samples was directly dependent upon the degree of maturity as indicated by the specific gravity. On the whole, the dehydrated products made from early-crop potatoes (from the southern region) ranked significantly lower in quality and general desirability than those from the late-crop potatoes (northern grown). This result is considered as due in part to the commercial custom of harvesting the early potatoes when the plants are still green and in part, possibly, to imperfect adaptation of the varieties. It is stressed that only fully mature potatoes should be used for dehydration.

A note on the blanching of potatoes, W. V. Cruess. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 9, p. 260*).—This note, concerned with the intent of a previous communication (E. S. R., 91, p. 480), points out that a slightly positive peroxidase test in dehydrated potatoes appears to have no great significance as to keeping quality provided the potatoes have been steam blanched sufficiently to cook them through without mushiness and to destroy most of the peroxidase reaction. Steam blanching is recommended in preference to water blanching.

Cooking dehydrated vegetables (*U. S. Dept. Agr., Bur. Human Nutr. and Home Econ., 1944, AIS–8, pp. 20*).—General directions for cooking so as to preserve the maximum of food value and flavor are presented, together with specific directions and recipes for cooking dehydrated potatoes, sweetpotatoes, carrots, beets, corn, peas, snap beans, spinach, broccoli, cabbage, cauliflower, onions, and mushrooms.

Wartime vegetable salting, F. W. Fabian. [Mich. Expt. Sta.]. (*Food Indus., 16 (1944), No. 5, pp. 72–74, 135, illus. 1*).—The process is described in detail with respect to both dry salting and brine methods. It is pointed out that vegetables should be blanched for salting, since the flavor of the final product is better than if unblanched vegetables are used. Vegetables should be stored in clean barrels, crocks, or tanks, and if wooden vessels are used they should be paraffined on the inside. Paraffined barrels completely filled are most satisfactory for commercial storage. All vegetables, whether salted dry or wet, ultimately should be covered with brine. Vegetables salted in open containers should be weighted to effect complete immersion. The tops of such containers should be covered with about 1 in. of paraffin to prevent scum formation and evaporation. The dry method of salting is particularly applicable to leafy vegetables which contain sufficient juice to cover them. Cucumbers, peppers, and tomatoes, because of their tough skins and soft interiors tend to collapse if dry salted and should be preserved in brines; cauliflower and onions, because of their lack of juice, should also be brine salted. High dry-salt concentrations are used for vegetables in which no fermentation is desired, as with corn, peas, and green lima beans, for example. Salt exerts a selective action on bacteria. In concentrations of 2.5 to 5 percent, rapid fermentation is generally permitted; higher concentrations, up to 15 percent, decrease the rate of fermentation. A concentration of salt greater than 20 percent is required to prevent spoilage.

Salting Early June and Alaskan peas, C. K. Wadsworth and F. W. Fabian. (Mich. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 10, pp. 298–301, 316*).—Previous work having shown that high salt concentrations must be used with brined peas (E. S. R., 89, p. 609), the tests here described were conducted with brine concentrations (calculated) of from 15 to 25 percent. At these concentrations, whether dry salt or brine was used, the bacterial counts were low and there was very little acid production. In dry salting it was necessary to distribute the salt thoroughly and evenly among the peas to prevent spoilage. It was also found necessary to supplement the dry salt with enough brine of the same concentration to cover the peas, since the dry salted peas did not produce enough brine to cover more than 80 percent of them and those left uncovered turned white and were useless. The salt penetrated the peas very quickly, 60 percent of it being taken up within 20–25 min. Conversely, the brined peas gave up their salt quickly, from 53 to 56 percent of that withdrawn in 150 min. of soaking being removed within 5 min. after placing the peas in cold water. Unblanched peas were tougher and had poorer color and flavor than blanched peas. Increasing the salt concentration increased the toughness of the peas, so that not over 20 percent salt was found desirable; at least 18 percent was necessary, however, to prevent spoilage. Analysis of the raw, blanched, and brined peas indicated that practically all of the ascorbic acid in the peas was lost during salting, but that carotene losses were relatively small; in some instances practically none of the carotene was lost, while in others as high as one-third of the original carotene content disappeared.

The utilization of green tomatoes, F. W. Fabian and C. K. Wadsworth. (Mich. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 12, pp. 361–362, 368*).—It is suggested that green tomatoes be salted or pickled in place of cucumbers in seasons when early frosts kill the cucumbers. Even several hard frosts that kill both the cucumber and tomato vines and injure the cucumbers often leave the green tomatoes uninjured. Sucessful experience in salting and pickling the green tomatoes and using them in green tomato relish is noted. Juices expressed from tomatoes at various stages of ripeness were analyzed for citric acid and ascorbic acid. The green tomato juice was unpalatable, but juices from the partially ripe fruits were acceptable.

The explosion vs. usual method of peeling vegetables and fruit, H. D. Brown and C. Murnane. (Ohio State Univ.). (*Amer. Soc. Hort. Sci. Proc., 44 (1944), pp. 190–192, illus. 1*).—The method developed involved subjecting fruits and vegetables placed in a retort with pressure and temperature controls to a temperature of from 212°–250° F. and a pressure of 0–15 lb., depending upon the product being peeled, and then drawing a vacuum of from 25–27 in. by shutting off the steam and rapidly forcing cold water into the top of the retort. Peppers, potatoes, sweetpotatoes, peaches, and apples were successfully peeled and lima beans freed of their pods by this method. Holding the temperature at 240° for 2 min., before the vacuum was created, effectively inactivated enzymes, so that the beans thus shelled were ready for quick freezing. Peeling losses for potatoes of several varieties peeled by the explosion method amounted to 7.6–12.8 percent as compared with 11.9–22.7 percent by the abrasion method. Losses for Stayman Winesap apples peeled by explosion and with a hand-operated peeling machine were 3.8 and 16.6 percent, respectively. The explosion method was particularly effective in removing skins from potato eyes, and apples cored by explosion needed no further trimming, especially if the skin was cut at the stem and blossom ends before explosion.

All patent rights for this process have been assigned to the Ohio State University Research Foundation.

Explosion method peels vegetables and fruit, H. D. BROWN. (Ohio State Univ.). (*Quick Frozen Foods, 6 (1944), No. 12, p. 30, illus. 1*).—Essentially noted above.

Commercial freezing of foods, J. G. WOODROOF. (Ga. Expt. Sta.). (*South. Canner and Packer, 5 (1944), No. 10, pp. 6–8, 20–21, illus. 3*).—This general survey of the processes and problems involved in the freezing of fruits and vegetables (including sweetpotatoes in particular) is based on Georgia Experiment Station Bulletin 233 (E. S. R., 91, p. 769).

Notes on frozen pack fruit syrups and concentrates, W. V. CRUESS. (Univ. Calif.). (*Canner, 99 (1944), No. 19, pp. 14–15; also in Fruit Prod. Jour. and Amer. Food Mfr., 24 (1944), No. 2, pp. 36, 61*).—A brief review of early and recent experiments at the California Station indicates that fruit sirups made by addition of sugar to the juice, to about 50° Brix, keep very well in frozen storage at 0° F. Fruit concentrates made by freezing concentration or vacuum concentration likewise remain practically unaltered in flavor, color, and aroma for long periods at 0°. The frozen products are recommended for the preparation of chilled beverages and the red concentrates in particular for use as bases for punches.

Freezing provides an answer to sweet potato problem, J. G. WOODROOF and I. S. ATKINSON. (Ga. Expt. Sta. et al.). (*Food Indus., 16 (1944), Nos. 7, pp. 79–81, illus. 2; 8, pp. 84–86, illus. 2*).—This paper outlines and presents a flow sheet of the steps involved in freezing sweetpotatoes. These steps applied to thoroughly cured sweetpotatoes include washing, grading, lye peeling and subsequent washing, inspecting and trimming, pressure cooking, pulping, filling into cans, and freezing at —20° F. The frozen sweetpotatoes stored at 0° offer a year-round supply of this vegetable. Grading is essential before processing, since the peeling and cooking steps are varied with the size, uniformity, and smoothness of the samples. Of the eight suggested methods of peeling (boiling water, salt solution, lye solution, baking, mineral oil, gas flame, abrasion, and hand peeling) a 5– to 6–min. treatment with 10 percent lye solution maintained at boiling temperature is recommended. The lye solution loses strength at the rate of about 1 lb. per bushel of sweetpotatoes peeled, and the sweetpotatoes lose about 30 percent of their weight in the peeling and trimming. Pre-cooking is best accomplished by steaming the peeled potatoes under 10–lb. pressure to an internal temperature of 190°.

The cooked sweetpotatoes may be frozen whole, sliced or as a pureè, but the latter form is preferred, since sweetpotatoes of all sizes above 1½ in. diameter may be used, storage space may be minimized, close trimming is not necessary, color is uniform, and measuring, weighing, and handling are facilitated. Discoloration of the puree is prevented by adding about 0.3 percent citric acid, which lowers the pH from the normal of 6.1 to 5 or below. It is estimated that sweetpotato puree can be prepared, frozen, and stored for 6 mo. for about 7 ct. a pound. Approximately three-fifths of the starch of the sweetpotatoes is converted to maltose in processing and from 2 to 5 percent of the total carbohydrate may be lost in leaching.

Frozen tomatoes not too good, juice has possibilities. (U. S. D. A.). (*Food Indus., 16 (1944), No. 8, pp. 87–88, illus. 1*).—In tests at the U. S. D. A. Western Regional Research Laboratory whole and sectioned tomatoes preserved by freezing tended to have a sharp, strong flavor, and when thawed collapsed severely. The texture breakdown was still more pronounced after the tomatoes had been cooked. A pulpy type, mild, highly colored, low acid tomato is recommended as the best for freezing. Only sound fruits of full-ripe maturity should be used. Skins and cores should be removed, and the whole or sectioned tomatoes should be packed, without blanching, into liquid-tight, air-resistant containers and frozen as rapidly as possible. Storage should be at temperatures around —10° F. Frozen tomato juice, which proved to be a better product than frozen tomatoes, was prepared by heating the cored fruit to 185° to 195° as rapidly as possible, expressing the juice with a screw-type expressor, cooling immediately, salting, packaging, and freezing quickly. Prepared in this way, the frozen juice retained a good color and a pleasant flavor which was somewhat different from that of canned juice. Sweet, low-acid varieties and sound, well-ripened, and full-flavored juices should be used for freezing. The greatest problem in freezing the tomato juice is the tendency for the liquid to separate from the pulp when thawed.

Experiments prove value of freezing baby foods, L. A. Hohl. (Univ. Calif.). (*Quick Frozen Foods, 6 (1944), No. 13, pp. 30, 36, illus. 1*).—Some of the problems involved in preparing and marketing frozen baby foods are discussed briefly. Tests on a laboratory scale with peaches, pears, and apricots indicated the necessity of blanching to prevent oxidative darkening and flavor deterioration and suggested a fruit : sugar ratio of 8 : 1 for peaches and pears and 3 or 4 : 1 for apricots. Because of their tartness, apricots were more satisfactory for baby foods if blended with milder fruits such as apples, peaches, or nectarines. Asparagus, beets, carrots, peas, green beans, and spinach, when precooked, pureed, and frozen, retained excellent color and flavor for storage periods of 1 yr. or more. Precooking, rather than blanching, is considered necessary for this type of product in order that the consumer would need only to thaw and warm it to the desired temperature before serving.

Blueberries for freezing improved by blanching, J. G. Woodroof and I. S. Atkinson. (Ga. Expt. Sta.). (*Refrig. Engin., 48 (1944), No. 4, pp. 275–278, 314, illus. 5*).—The woody texture developing upon storage of frozen blueberries was found to be prevented by blanching the berries preliminary to freezing. Blanching was successfully accomplished by passing the washed berries, in shallow layers, through a steam chamber for 1 or 2 min., or by immersing small lots of berries in boiling sirup containing 75 percent sugar for 15–20 sec., then allowing them to drain for 1 min. Histological examination of stained sections of the frozen berries showed the woody texture of the unblanched berries to be due to deposition of gritty material in the epidermal and subepidermal cells of the skins after about 6–mo. storage. This material continued to form for at least 2 yr. Steam blanching for 1 min. inactivated the enzymes causing this deposit, so that blanched frozen berries were improved in texture and tenderness (as determined by tenderometer tests); flavor, aroma, and palatability were also improved. The addition of dry sugar to blanched berries in the ratio of 5 : 1 improved the retention of flavor and other eating qualities. Woody texture was most pronounced in wild berries, slightly less in the Haygood and Ruby varieties, and considerably less in Rubel, Pioneer, and Cabot.

Blanching is essential, S. Bull. (Univ. Ill.). (*Quick Frozen Foods, 6 (1944), No. 12, p. 52*).—Blanching is stressed as a necessary step in preparing vegetables for quick freezing, in order to inactivate enzymes which if not destroyed will hasten undesirable oxidative changes in flavor and color and cause greatly increased vitamin loss.

What the locker plant operator should know about food poisoning, F. P. Griffiths. (Mass. Expt. Sta.). (*Quick Frozen Foods, 6 (1943), No. 5, pp. 45, 58*).—The rules enumerated emphasize the importance of using only the freshest, best quality foods for freezing, of blanching vegetables preliminary to freezing, of preparing and handling all foods under strictly sanitary conditions, of freezing them quickly in small-packing units, of storing at 0° F. or below, of preventing thawing and refreezing of food in locker storage, and of using the foods within a short time after removal from the locker.

The effect of harvest maturity on the canning quality of western-grown Elberta peaches, A. M. Neubert, M. K. Veldhuis, and W. J. Clore. (Wash. Expt. Sta. and U. S. D. A.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 10, pp. 292–297, 315, 317*).—This study to determine the best maturity range for harvesting peaches for canning was conducted with the Elberta variety grown in the Yakima Valley in 1940, 1941, and 1942. The effect of harvest maturity on size of fruit, bruising during handling, withering during ripening, and quality and yield of canned fruit were studied.

As the maturity at harvest increased, the flesh of the canned peaches gradually decreased in firmness, although fruit requiring from 3 to 14 days to ripen possessed a good firm texture. Fruit requiring more than 14 days to ripen was too hard, and that requiring less than 3 days was too soft. As maturity advanced until only about 6 days were required for ripening, flavor improved, but when less than 3 days was required the flavor was rather mild. The color of the canned fruit and the clarity of the sirup were not particularly associated with the maturity of the fruit at harvest. The peaches increased in size and weight at a rate of about 10 percent for each 3 days they were left on the tree. Peaches may be left on the tree without serious loss from bruising until within about 3 days of canning ripeness. The maturity at harvest did not seriously affect the peeling characteristics of the fruit.

"With all factors taken into consideration, the most satisfactory harvest maturity for Elberta peaches, as grown in the Pacific Northwest, was found when the fruit was about 75 percent yellow . . . and gave an average pressure test on peeled fruit of from approximately 4 lb. with a 7/16-in. plunger to approximately 9 lb. with a 5/16-in. plunger. Such fruit required from 3 to 7 days to ripen for canning. Color-picking, involving two or more harvests, would appear necessary to attain this maturity throughout a harvest."

The effect of storage on the canning quality of Elberta peaches, M. K. Veldhuis and A. M. Neubert. (U. S. D. A. and Washington Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 9, pp. 276–281*).—The effect of storage at 31°, 37°, and 45° F. on the canning quality of Washington-grown Elberta peaches was studied in the 1941 and 1942 seasons. The peaches were stored on trays in cabinets so constructed as to permit temperature and humidity control. The results of the study are summarized as follows: "Storage did not improve the canning qualities; but under the proper conditions the fruit could be held up to 3 or 4 weeks and still be acceptable. Peaches stored at 31° gave a satisfactory canned product after longer periods of storage than did the fruit stored at 37° or 45°. Steam-peeling characteristics of fruit stored at 31° remained satisfactory and the flavor of the canned product was better than that of fruit stored at 37° or 45° for the same length of time. The peeling characteristics of fruit stored at 37° and 45° became unsatisfactory in a short time. Riper fruits gave better results in storage at 31° than greener fruit."

If storage for canning is necessary, it is suggested that Elberta peaches be held as near 31° as possible and that the maturity of the fruit be within 5 days of full canning ripeness; if not this mature, it should be allowed to ripen before storage. The storage period should not be longer than necessary and should not exceed 4 weeks. Badly bruised fruit should not be stored.

Ripening Washington-grown Elberta peaches for canning, A. M. NEUBERT and M. K. VELDHUIS. (Wash. Expt. Sta. coop. U. S. D. A.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 12, pp. 357–360, 379, 381*).—Five different lots of commercially grown fruit in two maturity groups on the basis of color were ripened under a total of 24 ripening conditions during a 3-yr. period. One part of each lot of peaches was ripened in an open box at room temperature, one part was ripened in direct sunlight, and the rest was ripened in a cabinet under controlled conditions of temperature and humidity. The different portions were ripened at temperatures varying from 65°–95° F. and at high or low relative humidities (over or below 60 percent, respectively). After 2–3 days of ripening the peaches were observed for flesh color and ease of pitting and peeling and then canned. After 3–6 months' storage the canned samples were scored for quality.

Increasing the temperature of storage accelerated the rate of ripening and resulted in a deeper yellow color in the canned peaches. Wilting was an important factor only in greener peaches ripened above 85° under conditions of low humidity and in fruit ripened in direct sunlight. Peaches ripened in cabinets at 95° were difficult to steam peel. Freeness of the pit was not affected by any of the ripening conditions, but internal break-down occurred more frequently at the higher ripening temperatures. The most satisfactory ripening temperature was 75°; at this temperature the peaches attained a medium yellow color, were easily peeled, and reached a maximum flavor. The flavor of peaches ripened in open boxes at room temperature (70°–80°) was equal to that of peaches ripened in cabinets at 75°, but such fruit was lighter in color. At 75°, humidity did not appear to be a critical factor over the range ordinarily attained in normal practice. Ripening at low humidities, or at 65°, resulted in canned products of light yellow color.

Botulism from home-canned beets, B. L. HALL (*Jour. Lab. and Clin. Med., 29 (1944), No. 7, p. 702*).—A brief report is given of three cases of botulism, two with fatal outcome and the third with eventual recovery following treatment with botulinus antitoxin, from home-canned, incompletely sterilized beets from which, on examination, botulinus toxin type A was obtained.

Jellied fruits and vegetable sauces—postwar possibilities of low methoxyl pectins, G. L. BAKER. (Del. Expt. Sta.). (*Food Packer, 25 (1944), No. 8, pp. 31–32*).—This brief discussion, based on an extensive experimental survey noted elsewhere (E. S. R., 91, p. 638), of the effect of methoxyl content of pectins upon gel characteristics at different concentrations of sugar, gives a few examples showing how gels of low soluble solids content (30 percent) may be prepared.

Recent developments in fruit juices, W. V. CRUESS. (Univ. Calif.). (*Amer. Fruit Grower, 64 (1944), No. 11, pp. 11–12*).—This brief discussion points to the greatly increased production of canned fruit juices since 1935 to a high of 39,202,000 cases in 1943. Apple juice; fruit and vegetable juice blends, of which an orange-carrot blend was the most pleasing of those tested; an improved prune juice prepared by hot-water extraction of dried prunes; citrus juices; pineapple juice; grape juice; dried juices; frozen-pack juices; and concentrates, particularly those prepared by freezing concentration, are noted as among the most acceptable of the commercial fruit juice products.

Clouding and sedimentation in clarified apple juice, A. M. NEUBERT and M. K. VELDHUIS. (U. S. D. A. and Wash. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 11, pp. 324–328, 347*).—A total of 185 lots of pasteurized apple juice, including 57 control lots, was prepared, stored, and observed for sediment formation. The control juices were treated at room temperature for 15–24 hr. with Pectinol A (1 lb. per 100 gal.), filtered through duck with a filter aid, flash-pasteurized, bottled with no head space, sealed, cooled, and stored at room temperature. Treatment of other samples was varied by changing the filtration process, employing different pasteurization methods, varying the head space, and bottling with and without nitrogen or oxygen and by the use of various sedimentation methods. Of the 57 control juices, 5 remained clear for 12 mo. or longer and 5 became cloudy in 1 mo. The time between bottling and the formation of a cloud varied from 8 days to 2.5 yr. None of the other treatments afforded a dependable method for controlling or delaying sedimentation, which was quite general during storage of the products, regardless of the variety or maturity of the apples or the methods used to attain clarification. In general, juice clarified by pectin-decomposing enzymes deposited more sediment in a shorter period than did juices clarified by other methods. The period of stability of clarified apple juice appeared to depend on properties inherent in each particular lot of juice. These properties were not consistently controlled by any treatment studied. Analysis of the apple juice sediment showed it to be a rather inert substance similar in properties to the phlobaphenes. The formation of sediment appeared to be a colloidal phenomenon, and it is suggested that restabilization of the colloidal system after clarification offers the greatest hope for the control of the problem.

Bland apple sirup, H. H. MOTTERN and R. H. MORRIS, 3d. (U. S. D. A.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 9, pp. 261–269, 283–285, illus. 2*).—This report, superseding an earlier one (E. S. R., 88, p. 441), deals at length with the manufacturing process, including the equipment needed, production results, cost of manufacture, and composition of the product.

Changes occurring in orange and grapefruit juices during commercial processing and subsequent storage of the glass- and tin-packed products, E. L. MOORE, E. WIEDERHOLD, and C. D. ATKINS. (U. S. D. A.). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 9, pp. 270–275, 285, illus. 3*).—A comparison of parallel commercial packs of citrus juices in glass and tin showed orange and grapefruit juices as packed to contain 98–99 percent as much ascorbic acid as the freshly extracted juice. The slower cooling of the bottled juices apparently did not decrease the retention of ascorbic acid, although it resulted in a slightly cooked flavor in comparison with the canned juices. In storage over a 6-mo. period the bottled orange and grapefruit juices retained somewhat less of their ascorbic acid (75–92 percent) than the canned juices (82–97 percent), and among these samples those stored at 80° F. retained less than those held in a cool room at 40°. A small quantity of dehydroascorbic acid appeared to be present in the juices at the end of the storage period. In general, the juices held in the cold room for 6 mo. satisfactorily retained their color and flavor. At 80°, however, the orange juices in glass and tin were off-flavor, with the bottled juices slightly better in taste than the canned juice; the bottled grapefruit juice was considered unpalatable at the end of the storage period, but the canned juice was still satisfactory.

Concentration of citrus juice by freezing, A. L. STAHL. (Fla. Expt. Sta.). (*Quick Frozen Foods, 6 (1944), No. 13, pp. 32–33, 36, illus. 6*).—The concentration of the deaerated juice was effected by freezing out the water and separating the concentrate from the ice by centrifugation at about 2,500 r. p. m. for 3 min. By repetitions of the process, the concentration of dissolved solids was increased up to about 60 per cent, at which point an eutectic mixture was formed and the ice and dissolved substances solidified together. The liquid phase, after the first centrifugations, contained about 25 to 30 percent soluble solids, and after the second about 48 percent soluble solids. At this latter concentration, orange, tangerine, and grapefruit concentrates kept for 2 mo. at ordinary room temperature and for 4 to 6 mo. at refrigerator temperature without spoilage; storage in the frozen state was more satisfactory, however—very slight changes in flavor and vitamin C content occurring in 22 mo. in the frozen juice. The frozen block was reconstituted directly without thawing by addition of a measured amount of tap water equivalent to that removed from the juice. The best orange concentrate was made using Pineapple, Valencia, and seedling oranges. The seedy varieties of grapefruit gave better concentrates than the seedless varieties. All varieties of limes and lemons tested gave good juice concentrates.

Investigations on fruit bars, R. WHELTON, R. H. VAUGHN, and G. L. MARSH. (Univ. Calif. et al). (*Fruit Prod. Jour. and Amer. Food Mfr., 23 (1944), No. 12, pp. 363–364, 381, illus. 1*).—Plate counts by a procedure described to determine the microbial population of fruit bars showed that the number of organisms (bacteria, yeasts, molds) present in commercial fruit bars, even when unpasteurized, was relatively small. SO_2 in the form of potassium metabisulfite added to fruit bars to simulate the effect of sulfured fruit showed a marked toxic effect on added yeasts. This probably explained the low counts observed with unpasteurized commercial bars. The process time required to kill a heavy inoculum of *Zygosaccharomyces* in the center of the bar was found to be longer than the theoretical process time estimated from experimental data on the rate of heat penetration of individual bars and existing data on the thermal death time of various micro-organisms in solution. This protective action of the fruit bar against heat and the variations in rate of heat penetration under different conditions make it necessary for the plant to evaluate its required pasteurization time individually by measurement of the time of penetration of heat and, if possible, the killing of micro-organisms in the bars under factory conditions.

An investigation of methods for preventing the hardening of fruit bars in storage indicated the need for some sort of moistureproof wrap and the desirability of a protective coating that would withstand the heat of pasteurization or could be applied after the heat treatment with care to prevent contamination before wrapping.

Effect of acids and sugar on viability of Escherichia coli and Eberthella typhosa, C. A. SHILLINGLAW and M. LEVINE. (Iowa State Col.). (*Food Res., 8 (1943), No. 6, pp. 464–476, illus. 6*).—Studies undertaken to learn more about the behavior of intestinal organisms in acid solutions simulating soft drinks, in order to determine possibilities of transmission of water-borne diseases by such beverages, led to the following observations: In a concentration of 0.02 N, which is approximately that employed in many beverages, the order of effectiveness of edible acids as germicides against *Escherichia coli* at 30° C. was tartaric>glycolic>phosphoric>lactic>acetic>citric. The order of effectiveness of the acids at a temperature of 30° was tartaric>phosphoric>lactic>citric, and at 0.6° phosphoric=lactic>tartaric>citric.

Comparing the germicidal efficiencies of acetic, lactic, and glycolic acids, it appears that the substitution of a hydroxyl group for one of the hydrogens on the alpha carbon atom markedly increases the germicidal efficiency of an acid. The germicidal efficiency of 0.02 N lactic acid at 30° was increased by the addition of 2.5 volumes of carbon dioxide or 10 percent of sucrose. A concentration of 0.02 N citric acid at 30° required 57.5 hr. to kill 99.999 percent of exposed cells of *E. coli;* addition of 10 percent sucrose reduced the killing time to 32 hr.; incorporation of 2.5 volumes of carbon dioxide with the citric acid reduced the killing time to 17.5 hr. *Eberthella typhosa* was much more susceptible to the effect of CO_2 and edible acids than was *Escherichia coli.* A table is presented indicating the storage periods required to reduce various inocula of *E. coli* in 0.02 N edible acids with or without CO_2 or sugar to a point of compliance with the U. S. Public Health Service standards for drinking water.

The tidal air of laboratory animals, M. KLEIBER ET AL. (Univ. Calif. et al.). (*Science, 99 (1944), No. 2583, p. 542*).—A general formula is presented for determining tidal air on resting and fasting laboratory animals, and results are given of experimental tidal air determinations under conditions more nearly resembling those found during inhalation experiments with infectious nuclei. The tidal air of albino Swiss mice, as calculated from the metabolic rate, when deprived of food and water, decreased from the start of the fast. By the basic heat formula the tidal air of any laboratory animal can be quickly estimated if the weight is known. The data presented point out the need of having animals in a basal state in order to reduce the number of variables in inhalation experiments.

Blood: A review of the recent literature, F. H. Bethell, C. C. Sturgis, O. T. Mallery, Jr., and R. W. Rundles (*Arch. Int. Med., 74 (1944), Nos. 1, pp. 36–77; 2, pp. 131–152; 3, pp. 197–233*).—Of particular interest from the standpoint of nutrition in this extensive review are the sections on hypochromic anemia (pp. 50–57), anemia in pregnancy (pp. 57–58), and methods and miscellaneous material (pp. 227–233). Literature references are given as footnotes, of which there are more than 600 in the entire review and 37 in the section on hypochromic anemia.

The effect of measurement technics on the values for red cell diameter, with some observations on the relationship between cell diameter and other factors in the blood picture, J. M. Leichsenring, E. G. Donelson, and L. M. Wall. (Minn. Expt. Sta.). (*Amer Jour. Physiol., 141 (1944), No. 2, pp. 270–273*).—Measurements of red blood cell diameters made with a 4-mm. objective on a dry blood film gave higher values than similar measurements on a moist film; the diameters were lowest when measurements were made on a dry film with an oil immersion lens. This was demonstrated in several series of measurements, including one in which parallel determinations on eight samples by these three methods, respectively, gave average cell diameter values in microns of 7.747, 7.550, and 7.114.

A highly significant relationship between the diameter and the volume of the normal blood cells was found to exist; it was indicated by the coefficient of correlation secured between the values for these two cell characteristics obtained on 252 blood samples. In these 252 bloods, from women students, high red cell counts were associated with cells of relatively small size in normal blood samples, as shown by a significant negative coefficient of correlation between cell count and cell diameter. This report is presented as paper No. 22 of the Regional Project of the North Central States relating to the nutritional status of college women.

Effect of manganese intake upon concentration of bisulfite-binding substances in blood, J. T. Skinner and J. S. McHargue. (Ky. Expt. Sta.). (*Amer. Jour. Physiol., 141 (1944), No. 5, pp. 647–650*).—Young rats were placed as control animals on three rations containing respectively, 0.4, 0.3, and 1.5 p. p. m. manganese; others were raised on these rations supplemented, respectively, with manganese to the levels of about 8, 6, and 500 p. p. m. The concentration of bisulfite-binding substances in the blood of rats raised on the rations containing 0.3 and 0.4 p. p. m., respectively, was practically the same as that in the blood of animals receiving 20 times as much manganese. Rats consuming the rations low in magnesium as well as in manganese were found to have a higher average concentration of bisulfite-binding substances in the blood than rats fed a milk diet. This condition was not altered by supplementing the ration with a high intake (500 p. p. m.) of manganese.

The blood picture of iron and copper deficiency anemias in the rat, S. E. Smith and M. Medlicott. (U. S. D. A.). (*Amer. Jour. Physiol., 141 (1944), No. 3, pp. 354–358*).—"A deficiency of iron or copper or both produces an anemia in the rat that morphologically is classified as microcytic and hypochromic. The feeding of pure iron to milk anemic rats leads to a significant increase in the mean cell volume which, however, still remains less than normal. The feeding of copper to milk anemic rats produced a rise in the erythrocyte count which was not accompanied by an increase in hemoglobin."

The relationship of copper to hematopoiesis in experimental hemorrhagic anemia, A. R. MAASS, L. MICHAUD, H. SPECTOR, C. A. ELVEHJEM, and E. B. HART. (Wis. Expt. Sta.). (*Amer. Jour. Physiol., 141 (1944), No. 3, pp. 322–328, illus. 2*).—Young growing dogs on a raw milk diet supplemented with crystalline B vitamins and manganese were made severely anemic by repeated bleeding. Dietary administration of iron at various levels up to 30 mg. produced no response, but daily administration of 3 mg. copper brought about an immediate and rapid increase in hemoglobin, hematocrit, and red cell counts to normal values.

"An iron deficiency in the presence of adequate (3 mg.) copper caused a nutritional anemia and a concomitant decrease in mean corpuscular volume. The administration of 10, 20, or 30 mg. iron with 3 mg. copper gave the characteristic remission in the anemic dogs."

Comparative cost of vitamin mixtures (*Jour. Amer. Med. Assoc., 126 (1944), No. 1, p. 29*).—This report of the Council on Pharmacy and Chemistry of the American Medical Association contains a tabulation of the selling costs and declared contents of 25 multivitamin preparations offered in June 1944 in one of the largest department stores in the United States. The price values are given per package with the number of capsules in each package and also in rate per 100 capsules. For purposes of comparison, a table is also given of the daily vitamin requirements, including the National Research Council daily recommended allowances and the U. S. Food and Drug Administration recognized minimum daily requirements.

The vitamin value of commercially prepared chile products, E. M. LANTZ (*New Mexico Sta. Press Bul. 997 (1944), pp. [4]*).—Data are presented to show the carotene and ascorbic acid content of individual samples of commercially prepared canned green chili, pickled green peppers, green chili sauce, and red chili sauce. The products varied widely in ascorbic acid values in particular. The canned green peppers, for example, ranged from practically nothing to almost 200 mg. of ascorbic acid per 100 gm., with carotene values ranging from 0.24–0.55 mg. per 100 gm. The red chili sauces were likewise variable in ascorbic acid content, ranging from 0–58 mg. per 100 gm.; carotene values were higher than in the canned green chili, varying from 1.5–26.1 mg. per 100 gm. Samples of heavy puree of fresh red chili pods supplied by the processor for analysis and used commercially as a base for the red chili sauce contained from 147–195 mg. of ascorbic acid and approximately 10–12 mg. of carotene per 100 gm. The products prepared from dried red chili contributed comparatively high amounts of vitamin A, but practically no ascorbic acid.

Fortification of milk with vitamins and minerals (*Jour. Amer. Med. Assoc., 126 (1944), No. 7, pp. 432–433*).—This discussion sets forth the reasons for the conclusion of the American Medical Association's Council on Foods and Nutrition that the "fortification of milk with vitamin A, thiamine, riboflavin, niacin, iron, and iodine or any one of these materials does not serve a public health need sufficiently to warrant Council acceptance of the fortified product."

Clinical adequacy of a single measurement of vitamin A absorption, E. L. PRATT and K. R. FAHEY (*Amer. Jour. Diseases Children, 68 (1944), No. 2, pp. 83–85, illus. 2*).—From a study of the rates of absorption of vitamin A for 112 patients, aged 4 weeks to 12 yr., with chronic disturbance of nutrition, it is concluded that for patients in this particular age group a single determination of vitamin A and carotenoids in the blood, taken 4 hr. after the administration of a test dose of percomorph liver oil for infants under 6 mo. of age or 5 hr. after the test dose for older children, provides information concerning the rate of absorption of vitamin A of the same clinical value as that obtained from more frequent determinations. Extensive reduction in the ability to absorb vitamin A was found to characterize pancreatic fibrosis and celiac disease. A review of the individual

VOL. 92 MAY 1945 No. 5

RECENT WORK IN AGRICULTURAL SCIENCE[1]

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

The chemical composition of maturing New York State grapes, Z. I. KERTESZ (*New York State Sta. Tech. Bul. 274 (1944), pp. 13, illus. 1*).—The pH, acid content, specific gravity, and sugar content of several varieties of grapes grown in four districts in New York State were determined, together with the total soluble solids content of the juice expressed from the grapes as measured by a hand refractometer. From these data the sugar-acid ratio and the difference between the total soluble solids content and the true total sugar content were computed.

None of these characteristics appeared suitable to define the maturity of grapes of any given variety. Seasonal variations and differences due to location were shown to be much larger than those which occur between grapes not fully ripe and those which have attained full maturity.

The hand refractometer was found to be an instrument useful in determining the total soluble solids content of the juice pressed from grapes. It was shown to give results practically identical with those obtained by the Balling hydrometer. Correction factors for the estimation of the approximate true sugar content from the proportion of total soluble solids content in several important varieties of grapes are given.

Studies on the fractionation of zein, R. A. GORTNER and R. T. MACDONALD. (Minn. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 4, pp. 324–333, illus. 1*).—The authors describe a method of fractionating zein in methyl cellosolve solution by addition of water wherein several fractions have been obtained. One of these fractions (Fraction A, thrown down by addition of 31 percent of water by volume) was subjected to a process of refractionation which resulted in a further set of subfractions.

These experiments indicated two types of protein in zein. Type 1, hydrophobic, is precipitated as a compact coagulum. Type 2, hydrophilic, is not precipitable by water but forms a stable suspension when thrown out of clear solution. These two zein proteins were found to differ markedly in their total nitrogen content. Optical rotations of four of the zein fractions indicated at least three components. Their osmotic pressures indicated considerable variation in their molecular weights. These results, together with information obtained from peptization studies and from the weights of individual fractions obtained in the original separation, led to the conclusion that in zein: (1) 65 percent of the total protein consists of a fraction of molecular weight 45,000; (2) 25 percent of the total protein is a fraction of molecular weight 30,000; and (3) 10 percent of the total protein is a fraction of molecular weight 23,350. The third protein fraction is of type 2, whereas the others are of type 1.

---

[1] **The publications abstracted in these columns are seldom available for distribution by the Office of Experiment Stations. In general, application should be made to the Office of Information of the U. S. Department of Agriculture, Washington 25, D. C., for publications of the Department; to the directors of the State agricultural experiment stations, as listed on page 3 of the cover of this issue, for publications of the several experiment stations; and to publishers of books and journals for material issued by them. Microfilms and photostatic copies, the latter legible without magnifying equipment, may be purchased from the Library, U. S. Department of Agriculture, Washington 25, D. C. Rates and other details are explained in a previous issue (E. S. R., 87, p. 324).**

A comparative study of the development of amylases in germinating cereals, E. KNEEN. (Nebr. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 4, pp. 304–314*).—β-Amylase was found in relatively high concentrations in ungerminated barley, wheat, and rye and in much less quantity in oats. The method used was not sufficiently sensitive to detect this enzyme in ungerminated maize, sorghum, or rice. From one third to one half of the total (papain-extractable) amylase was readily extracted by dilute calcium acetate solution. All the ungerminated samples had α-amylase activity but in relatively minor degree.

Germination of all the cereals led to a pronounced increase in α-amylase activity. The β-amylase of barley, wheat, and rye became more readily extractable. The β-amylase activity of germinated rice, though low, could be evaluated, but the quantities of this enzyme in germinated oats, maize, and sorghum were below the sensitivity of the customary methods. The small quantity of β-amylase present in oats largely disappeared during the germination process. When "absolute" changes in amylase activities were calculated for all the samples, it became apparent that in barley, wheat, and rye, a marked loss of β-amylase occurred during germination. Temperatures normally considered desirable for malting wheat inhibited sorghum germination. The significance of this relationship in a comparison of amylase development during the germination of different cereals was pointed out.

Industrially, the availability of cereal preparations having almost any desired combination of α- and β-amylase may have some significance. A malt having high α-amylase activity and practical freedom from β-amylase could be prepared from sorghum, and one having both α- and β-amylase from barley. The ungerminated barley itself provides a source of β-amylase relatively free from the α form.

Production of starch from wheat and other cereal flours, R. J. DIMLER, H. A. DAVIS, C. E. RIST, and G. E. HILBERT. (U. S. D. A.). (*Cereal Chem., 21 (1944), No. 5, pp. 430–446, illus. 5*).—As a basis for the production of starch from flour, conditions have been established for the essentially complete dispersion of the protein of wheat flour, without materially affecting the starch, by treatment with dilute aqueous sodium hydroxide. Two representative procedures, centrifuging and tabling, were used for starch separation. The alkali process, as used for wheat flour, was applied also to barley, rye, oat, corn, sorghum, and rice flours. These raw materials, under the conditions used, were not as satisfactory as wheat flour.

The tabling process yielded a prime-quality starch fraction, equivalent to 70–80 percent of the starch in the wheat flour. The remainder of the starch is recovered as a lower-quality fraction of low protein content (0.4–0.7 percent) and suitable for certain conversion or fermentation uses. The centrifuging process isolated all the starch of the wheat flour in a single fraction having a protein content of 0.4–0.6 percent. Included in this product are other alkali-insoluble solids which reduce the purity of the starch to between 94 and 98 percent.

The recovered byproduct wheat protein has a purity of 70–90 percent and constitutes 50–80 percent of the flour protein.

Gelatinization studies upon wheat and other starches with the amylograph, C. A. ANKER and W. F. GEDDES. (Minn. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 5, pp. 335–360, illus. 5*).—Response of the amylograph to variations in the load applied to the viscosity-registering device was essentially linear. Wheat starch suspensions gelatinized in the amylograph from initial temperatures above 45° C. gave markedly higher peak viscosities than corresponding suspensions gelatinized from lower initial temperatures. The precision of the measurement is satisfactory. The amylograph appears to provide a convenient means of investigating the pasting properties of starches from various sources, the relative resistance of different starches to amylases and other starch degrading agents, and the effects of different processing treatments. Caution must be observed in interpreting the maximum paste viscosity of wheat- and rye-flour suspensions as an index of relative α-amylase activity of the flours because of the influence on paste viscosity of such variables as starch content, protein content, inherent differences between starches, extent of mechanical injury, and pH.

With an increase in starch concentration, the temperature of transition and paste temperature at maximum viscosity decreased, the maximum paste viscosity increased, and the rate of decrease in viscosity after the maximum became greater. When the logarithm of the maximum viscosity was plotted against the logarithm of the starch concentration, a straight line resulted for all starches investigated (corn, potato, and wheat). This relation implies that starch swelling is a first-order process while granule disintegration is a process of the second or of a higher order.

Stored and damaged wheats for starch production, M. M. MACMASTERS and G. E. HILBERT. (U. S. D. A.). (*Cereal Chem., 21 (1944), No. 4, pp. 258–266*).—Wheat stored for 3–15 yr. in a cool, dry, well-ventilated place in the laboratory or in farm bins was found to be suitable for starch production. Recovery of starch seemed to decrease somewhat as the wheat aged, but so far as determined, the properties of the starch were not found to be altered. Common types of damage to wheat, other than severe heating, were shown not to unfit it for starch production. A few types of damaged wheat yielded starch having a slight off-odor. Only in badly heat-damaged wheat were the properties of starch found to be modified.

The effect of temperature differences on some mixogram properties of hard red spring wheat flours, R. H. HARRIS, L. D. SIBBITT, and G. M. SCOTT. (N. Dak. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 5, pp. 374–385, illus. 6*).—Curve height and width were decreased by increasing the temperature. Dough development period was also markedly reduced by increasing the temperature except in the case of curves made with baking formula doughs at temperatures above 30° C. This appeared to be due chiefly to the low form of the mixer patterns. Varietal differences were more pronounced when the flours were mixed with the ingredients of the baking formula than when water alone was used. The effect of temperature on curve height and width was not uniform for flours representing different varieties. Dough development stage, however, varied with temperature in essentially the same manner for all varieties. The effect of temperature variations on mixer patterns differed for flour-water and baking formula doughs. Differences in protein content were less effective in changing curve properties than were temperature variations. Curves resembling those of normal protein hard red spring wheat flours may be obtained from low protein flours by making the recordings at a lower mixing temperature. An increase in the flour absorption decreased curve height, and, to a lesser extent, curve width, but the dough development stage was increased.

Effect of bran on bread baking, M. R. SHETLAR and J. F. LYMAN. (Ohio State Univ.). (*Cereal Chem., 21 (1944), No. 4, pp. 295–304, illus. 3*).—Three samples of bran were so ground that the five different granulations prepared from each ranged in average particle size from 0.06 mm. in diameter in the finest grinding to 2.66 mm. in the coarsest. These brans were superimposed at the rate of 15 percent on three different bread flours and the resulting mixtures baked, in a slightly modified American Association of Cereal Chemists procedure.

The effect of the addition of bran on loaf volume varied with the different flours, but the three brans produced similar results. A high negative correlation between loaf volume and bran-particle size was found. At the level used, coarse bran caused a very significant decrease in loaf volume, while the finest granulations caused a barely significant increase in loaf volume when compared to the corresponding control loaves. Bran contains a water-soluble substance which when added to white flour doughs increases loaf volume. Water-extracted bran decreased loaf volume to about the same extent as did ground cellophane when added to flour at the same stage of granulation. The results indicated that bread of good volume and texture can be produced from flour containing finely ground bran.

An instrument for determining the compressibility and resistance to shear of baked products, Y. F. Combs (*Cereal Chem., 21 (1944), No. 4, pp. 319–324, illus. 3*).—Compression is effected by a circular disk made small enough to cover the more uniform central portion of the slice without covering any of the firmer area close to the crust. This disk is united by a ball-and-socket joint to a vertical sliding rod carrying a platform at its top. A flask placed upon the platform receives lead shot from a receiver controlled by a solenoid-operated valve so connected that the solenoid current is cut off and the valve permitted to close when the compression disk has been forced down through a fixed distance. This fixed depression is indicated by a magnifying lever needle traveling over a graduated sector. The weight of the shot required to effect the fixed degree of compression is added to the known weight of the flask, platform, shaft, and compression disk to give the total weight causing the depression. A frame carrying three wires may be substituted for the compression plate to permit measurement of shear resistance.

Correlation between chemical structure of some organic compounds and their action as flour improvers and as inhibitors of proteolytic enzymes, E. Elion (*Cereal Chem., 21 (1944), No. 4, pp. 314–319*).—Organic compounds, whether aliphatic or cyclic, which contain the group ·C(OH) : C(OH)·CO., were found to act as inhibitors of papain. Examples of such organic compounds, some with strong reducing properties, are given and they were found to act in a manner similar to that of ascorbic acid. Such compounds also act as flour improvers, although their use as such may be impossible because some of these compounds may prove poisonous and some have an undesirable effect on color or other bread properties.

The growth of bacteria with a constant food supply.—I, Preliminary observations on Bacterium coli, R. C. Jordan and S. E. Jacobs (*Jour. Bact., 48 (1944), No. 5, pp. 579–598, illus. 3*).—The authors cultivated *B. coli* in an apparatus which permitted rigid control of temperature, pH, aeration, and culture volume, and also allowed food to be supplied at any desired rate by means of an automatic syringe mechanism. They made determinations of total and viable cell populations and constructed growth curves.

At each of the two rates of constant food supply used, an initial period in which the total and viable counts were both increasing was followed by a steady phase in which the viable counts remained constant or decreased slightly while the total cell counts steadily increased. When, in experiments which had reached the steady phase, the food supply was suddenly doubled, a second phase of cell multiplication similar to that in the initial period began and was succeeded by a second steady phase. When, during the first steady phase, the food supply was suddenly stopped, the total cell population remained constant but the viable cells decreased to a constant low level. Approximate calculations of the quantity of food used in the formation of a new *B. coli* cell and in maintenance of a cell apart from reproduction indicated 1.1×10^{-9} mg. and 0.4 to 0.5×10^{-9} mg. per 25 hr. of a dehydrated broth, respectively.

The bacterial oxidation of corn oil, J. O. Mundt and F. W. Fabian. (Mich. Expt. Sta.). (*Jour. Bact., 48 (1944), No. 1, pp. 1–11, illus. 1*).—The authors found the Warburg apparatus to be a dependable, timesaving instrument in determining the ability of bacteria to take up oxygen in the presence of fats and oils. It yielded information not made available by culture or by chemical tests.

Of 32 cultures of commonly occurring soil and water bacteria studied, it was found that 25 showed an increased rate of utilization of oxygen while only 6 evinced the ability to dehydrogenate the oil. To *Aerobacter aerogenes* (the only species reported to date to be fat-oxidative and nonlipolytic) may be added *Alkaligenes faecalis, Sarcina lutea, Micrococcus aurantiacus, M. flavescens, M. cinnabareus, Flavobacterium arborescens, Phytomonas tumefaciens,* and *Pseudomonas mephitica.* On prolonged incubation, the oxidative changes of lipides brought about in flasks containing bacteria are indistinguishable from strictly nonbiological changes, as shown by determinations of the various fat constants. A concentration of 0.85 percent NaCl brought about a noticeable inhibition in the rate of respiration for three of six species of *Pseudomonas.* A concentration of 2.5 percent inhibited the respiration of all species except *P. fluorescens,* in the presence of oil, to a point below that of endogenous respiration in saline-buffer suspension. The respiratory rate was lowered by a decreased pH, but a comparatively low pH (about 5.0 to 5.6) was required to bring about a noticeable inhibition. Two anti-oxidants, hydroquinone and a commercial preparation, did not prevent bacterial respiration in the presence of oil in the concentrations used.

An alcohol oxidation system in streptococci which functions without hydrogen peroxide accumulation, E. C. GREISEN and I. C. GUNSALUS. (Cornell Univ.). (*Jour. Bact., 48 (1944), No. 5, pp. 515–525, illus. 3*).—The authors showed that *Streptococcus mastitidis,* a homofermentative lactic acid organism lacking the usual hemin catalysts, oxidizes ethyl alcohol to acetic acid in the presence of air without added carriers. The rate of oxidation is stimulated several fold by the addition of methylene blue. The oxidation requires but 1 mole of oxygen per mole of alcohol, and hydrogen peroxide does not accumulate in the absence of added carriers. When semicarbazide is added as an aldehyde fixative, alcohol is oxidized more rapidly with the utilization of 0.5 mole of oxygen per mole of alcohol. Aldehyde is oxidized to acetic acid by 0.5 mole of oxygen. In the absence of oxygen, aldehyde is dismutated to acid and alcohol.

The author's experiments further show that the alcohol oxidation is inhibited by M/100 iodoacetate, but neither the aldehyde oxidation nor the dismutation is thus inhibited. Sodium cyanide does not inhibit the oxidation at the concentration effective against the usual hemin systems but does partially inhibit at M/100.

Citric acid fermentation by streptococci and lactobacilli, J. J. R. CAMPBELL and I. C. GUNSALUS. (Cornell Univ.). (*Jour. Bact., 48 (1944), No. 1, pp. 71–76*).—Several species of homofermentative lactic acid bacteria, cocci, and rods were shown to utilize citric acid as an energy source for growth in the absence of fermentable carbohydrate. Fermentation balances of growing cultures of representative strains of enterococci, *Lactobacillus delbrueckii,* and *L. casei* showed the main products in neutral cultures to be acetic acid and carbon dioxide, formic and lactic acids accounting for most of the remaining carbon. Traces of acetylmethylcarbinol and ethyl alcohol were also formed. With citric acid as substrate, the fermentation products of the homofermentative lactic acid bacteria show several similarities to those formed by members of the *Leuconostoc* and *Aerobacter* genera.

It is suggested that oxidized substrates, such as citric acid, will give more information as to the potentialities of the homofermentative organisms than will the more conventional hexoses.

A chemical and immunological study of the capsular polysaccharide of Clostridium perfringens, M. H. SVEC and E. MCCOY. (Univ. Wis.). (*Jour. Bact., 48 (1944), No. 1, pp. 31–44*).—The authors describe a method of isolation of the capsular polysaccharide of *C. perfringens* involving cultivation of the organism in large volumes of a synthetic medium, high speed centrifugation, reduction to less than one-eighth of the original volume under reduced pressure at 22°–27° C., removal of an ammonium sulfate precipitate, ultrafiltration of the filtrate from this precipitate, further concentration, removal of ammonium sulfate by dialysis, precipitation by methyl alcohol, flocculation of the precipitate with a very small quantity of acetic acid, and washing of the precipitate with absolute methyl alcohol. They obtained 3.5128 gm. polysaccharide from 25 l. of culture. Analyses of preparations secured by variations on this method were made.

Antigenicity of three of these preparations was established. Precipitation and agglutination tests indicate a common capsular polysaccharide for most, if not all, strains of *C. perfringens*. It is recommended that, if possible, serums for agglutinations be prepared by injection of polysaccharide adsorbed upon some inactive carrier to avoid, whenever practicable, the use of whole cells as antigens. Agglutination reactions with such serums are suggested as aids in diagnosis of *C. perfringens* in gas gangrene, or in classification of this organism, with the reservation that the procedure indicates nothing concerning the fermentative or toxigenic capacities of the strain under consideration.

Ashing of egg whites and yolks and the determination of their iron content, S. L. Bandemer, J. A. Davidson, and P. J. Schaible. (Mich. Expt. Sta.). (*Poultry Sci., 23 (1944), No. 5, pp. 437–440*).—The whites were placed in folded filter papers within crucibles and charred over Meeker burners. Magnesium chloride was then added and the ashing was completed in a muffle furnace overnight at 600° C. Difficulties encountered were attributed to the high ratio of phosphorus to base in the white, as when various phosphorus compounds were added to iron solutions in the proportion found in egg white the ash fused and the iron was incompletely recovered. If magnesium chloride was added before the material was placed in the muffle furnace, no fusion occurred and the iron was completely recovered. With the small samples of yolk ashed, no difficulty was experienced. For larger yolk samples, the use of folded filter paper in the crucible was found advantageous.

An aid in ashing certain materials, S. L. Bandemer and P. J. Schaible. (Mich. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 6, p. 417, illus. 1*).—For substances that are finely ground, contain oil or fat, or have a high phosphorus-to-base ratio, the method above described as suitable for egg white is suggested.

Carbon dioxide generator for the Dumas method of determining nitrogen, H. A. Pagel. (Univ. Nebr.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 5, pp. 344–345, illus. 1*).—The author finds the generator here described to have as its advantages a generating capacity of over 650 l. of gas, exclusive of the amount wasted during the initial evacuation to remove air impurities; the bicarbonate solution is automatically agitated whenever more gas is generated, whereby stratification is avoided; any traces of residual air in the acid reservoir are effectively swept out whenever the gas is used; no special safety precautions are necessary during the initial evacuation or later operation; and since the gasometer (with a flexible glass extension) is an integral part of the generator, the two rubber couplings ordinarily used are eliminated from the train. The chief disadvantage is that certain parts (particularly the generator bottle, acid reservoir, and gasometer) must be rigidly supported to prevent breakage due to possible misalignment after the parts are assembled. The apparatus is, however, safely portable when mounted on a suitable platform.

Rapid digestion method for determination of phosphorus, D. W. Bolin and O. E. Stamberg. (Idaho Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 5, p. 345*).—The authors have shown that the presence of molybdenum in a perchloric-sulfuric acid mixture markedly increases the rate of oxidation of organic matter. The use of molybdenum in small quantities as catalyst proved not to interfere with the quantitative colorimetric determination of phosphorus as in the Fiske and Subbarow method (E. S. R., 55, p. 310). Hence a rapid method was developed for determining phosphorus by perchloric-sulfuric acid digestion (E. S. R., 75, pp. 153, 156) in the presence of molybdenum followed by colorimetric analyses. Results of phosphorus determinations on feeds digested with perchloric-sulfuric acid mixture in the presence of molybdenum as a catalyst are presented and compared with results obtained by the official ashing method. Digestion of the sample to a clear solution free from charred residue could usually be effected in a few minutes. When samples were of 0.5 gm. or less a set of six samples could be digested in less than 10 min. The examples given are of analyses of feeds and their component materials.

Colorimetric determination of 2,4-dinitroanisole, M. S. SCHECHTER and H. L. HALLER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 5, pp. 325–326, illus. 2*).—Use was made of the purpuric acid reaction, in which potassium cyanide reacts with *m*-dinitro compounds to give red-brown to violet colors. The reaction with 2,4-dinitroanisole is presumed to be similar to that for 2,4-dinitrophenol, which gives 2-hydroxylamino-3-cyano-4-nitrophenol. A reaction of the dinitroanisole in which it is acted upon by concentrated sodium hydroxide in acetone solution to give a violet color was found to be too sensitive for samples containing as much as 2 percent of 2,4-dinitroanisole, but it is held that this reaction would certainly be useful when very small quantities of 2,4-dinitroanisole had to be determined.

Colorimetric determination of 1-chloro-2,4-dinitrobenzene as an impurity in 2,4-dinitroanisole, M. S. SCHECHTER and H. L. HALLER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 5, pp. 326–327, illus. 1*).—The method described is based upon the reaction of 2,4-dinitrochlorobenzene with pyridine in which the ring is opened to give a 2,4-dinitrophenylimine of an open-chain unsaturated aldehyde. This aldehyde, in the enol form in which it exists in alcoholic alkaline solution, is of an intense violet color. The intensity of this color is determined in a photometer with the aid of a [Wratten?] No. 58 light filter.

A colorimetric determination of nicotinic acid, A. E. TEERI and S. R. SHIMER (*New Hampshire Sta. Sci. Contrib. [92] [1944], pp. 307–311*).—This has been abstracted (E. S. R., 91, p. 637) from the original.

In line 7 of the second paragraph of that abstract, the numerical expression of wavelength should read "400 mμ."

Adsorption of riboflavin by lactose, A. LEVITON. (U. S. D. A.). (*Indus. and Engin. Chem., 36 (1944), No. 8, pp. 744–747, illus. 1*).—In continuation of earlier work (E. S. R., 90, p. 442) dealing with the influence of concentration on the adsorption of riboflavin by lactose, the present study shows that temperature is very important, since temperature as well as lactose concentration influences the critical concentration of riboflavin below which no adsorption occurs. This critical concentration was found to increase markedly with temperature increase, so that by choosing a temperature sufficiently high it was possible to crystallize a considerable portion of the lactose free of riboflavin. Then by lowering the temperature it was possible to crystallize another batch of lactose containing adsorbed riboflavin in good yields. Tables are given from which the plant operator may choose operating conditions with respect to concentration and temperature for the controlled preparation of adsorbate in the yield and concentration desired. As a basis for these tables, concentrations and temperatures were studied that covered the ranges encountered in the manufacture of adsorbates from grain curd casein.

Some factors affecting the determination of riboflavin by the fluorometric method, A. HOFFER, A. W. ALCOCK, and W. F. GEDDES. (Minn. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 6, pp. 515–523*).—The reference assay procedure used was essentially that of Andrews (E. S. R., 91, p. 506) and involved utilization of a 1-gm. sample and adsorption of riboflavin from the extract (following $KMnO_4$ and H_2O_2 treatment), using Florisil as the adsorbent. The effect of sample size was studied by observing the adsorption from 50 cc. aliquots of extract (100 cc. total value) prepared from 3, 6, and 10 gm. of second-clear flour and passed in succession through a series of four adsorption tubes containing 1.1 gm. Florisil.

In a parallel series of experiments different volumes of extract were each passed through a series of four adsorption tubes. As the sample size increased a smaller fraction of the total riboflavin of the extract was adsorbed on the first tube and as the size of the aliquot increased more and more riboflavin escaped adsorption on the first tube. With the larger samples (6 and 10 gm.) the proportion of the riboflavin adsorbed when adsorption was apparently complete was only about 50 percent of that observed for the smaller samples. These results indicated that increasing the size of sample decreased the efficiency of extraction and also decreased the adsorptive efficiency of the Florisil. Riboflavin adsorbed on extraction residues went into solution upon dilution. Different lots of Florisil exhibited differences in adsorptive efficiency, but even the less efficient Florisils adsorbed pure riboflavin quantitatively from aqueous or buffered acid solutions; the lowered efficiency with flour extracts as sample size increased suggested, therefore, that increasing quantities of impurities were present in the extract.

Taking this factor into account, suggestions are made for carrying out recovery trials and for checking the adsorbing qualities of Florisil. Native riboflavin adsorbed on Florisil could be removed by washing, indicating the necessity for using the minimum of washing water. "The use of Corning filter 511 alone for the incident light proved unsatisfactory owing to the photosensitivity of riboflavin in pyridine eluates and to the difficulty of finding the blank values for patent flour eluates. The use of a combination of Corning filters 511 and 038 for the incident light with 351 for the fluorescent light eliminated these difficulties as sources of important errors."

A rapid method for the determination of riboflavin in wheat and wheat products, A. Hoffer, A. W. Alcock, and W. F. Geddes. (Minn. Expt. Sta.). (*Cereal Chem., 21 (1944), No. 6, pp. 524–533*).—The rapid method described eliminated adsorption on Florisil and the use of pyridine, and involved extraction of the riboflavin by heating the sample in acid KCl solution for 30 min. at 70° C. From the supernatant solution, separated from the residue by centrifugation, an aliquot was taken for treatment with $KMnO_4$ and H_2O_2 for removal of impurities. Fluorescence, read after the gas bubbles had cleared, was measured before and after the addition of the riboflavin standard to the aliquot and again following treatment with sodium hydrosulfite to obtain the blank reading. Results of assays of flour, mill feeds, and bread by the rapid method agreed closely with those obtained by the fluorometric procedure described above, which was used as a standard of reference. For both the rapid and reference methods the absolute error increased, while the percentage error decreased, with increasing riboflavin content. The duplicate error for the rapid method was lower than for the reference method. The rapid method worked well with enriched flour and bread, mill feeds, and wheat, and in spite of low fluorescence readings gave satisfactory results for unenriched patent flours. It is considered applicable to other materials but not to green plant tissues. A single determination by this method required from 60–70 min.

Simplification of the thiochrome method for thiamine determination, G. W. Schiller (*Cereal Chem., 21 (1944), No. 6, pp. 544–548*).—The procedure described effects a considerable saving of time by elimination of the zeolite adsorption procedure. The method was found applicable without variation in procedure to all types of milled products, and no correction factors were necessary. The sample, varied in weight depending upon the expected thiamine content, is subjected to warm acid hydrolysis followed by adjustment of pH and hydrolysis with takadiastase. The extract obtained upon filtration is treated with KCl crystals and then subjected to oxidation with alkaline ferricyanide, the alkali being added after the ferricyanide, following which the fluorescent material is extracted with isobutanol; fluorescence readings are made directly from this extract (after drying with anhydrous sodium sulfate) in the fluorophotometer previously set with the quinine sulfate standard. The reading obtained is proportional to the amount of thiamine in the sample plus any nonthiamine fluorescent impurities. The latter are corrected for in readings from the blank determination carried out with the unknown subjected to all treatments except that of oxidation. The thiamine content is calculated, according to the equation given, with reference to readings obtained on a thiamine control solution subjected to the various treatments in the procedure. The accuracy of the simplified method, as shown by collaborative analyses of 127 samples of various cereal products, compares favorably with that of the regular thiochrome method.

Properties of paraffin relating to microtechnique, W. T. DEMPSTER (*Mich. Acad. Sci., Arts, and Letters, Papers, 29 (1943), pp. 251-264, illus. 5*).—"Unadulterated paraffin, when congealed in an embedding mass, is composed of contiguous needlelike crystalline aggregates, each of which consists of a central core and many concentric lamellae made of alternate depositions of hard and soft paraffin. This crystalline mass forms the matrix for embedded tissue. Except for the most peripheral layer, rapid cooling of a mass does not materially reduce the size of crystals. If each crystal is in intimate contact with other crystals so that no interstices occur, the paraffin is clear and homogeneous, and good microtome sections may be made. Mottling or 'crystallization' is a defect due to air spaces between crystals, which makes crystals visible grossly. Suggested procedures that eliminate or reduce mottling are outlined. Within tissue interstices typical needle structure of paraffin is supplanted by irregular lamellation, but within cells the paraffin is amorphous. Cooling curves are presented to show characteristics of a group of typical embedding paraffins. The literature on paraffin transition points is cited in relation to a discussion of the plastic behavior of paraffin. Above and below a characteristic temperature for each paraffin the mode of response to a distorting force becomes altered. This temperature, for standardized conditions of testing, may be called the plastic point, and it may be used as a measure of the relative hardness of paraffin. The sectioning behavior of paraffin is more closely related to the plastic point of a sample than to the melting point."

Un nouveau micromanipulateur hydraulique, M. CAILLOUX (*Rev. Canad. Biol., 2 (1943), No. 5, pp. 528–540, illus. 7; Eng. abs., pp. 539–540*).—The new type of apparatus described and illustrated is composed of two distinct units—the micromanipulator and the receptor which holds the microtools. The advantages reported are: All movements of the tools are controlled by a single knob; the response is positive, without lag; it is exceedingly refractory to vibrations; the receptor can be so placed that the microtool seems to be a continuation of the lever on the manipulator; the ratio of demultiplication can be varied at will; the apparatus does not need previous training for expert application; and in its manufacture very few parts need be machined with great precision.

AGRICULTURAL METEOROLOGY

Weather predetermined by solar variation, C. G. ABBOT (*Smithsn. Misc. Collect., 104 (1944), No. 5, pp. 44, illus. 24*).—From revised daily solar-constant values studied to select dates during 1924–39 when brief sequences of rise and fall of the sun's emission of radiation occurred, a table of 440 sequences was made; this table is divided into cases of rising and falling sequences, and each class is then subdivided into 12 groups for the 12 mo. of the year. The average length per sequence is 4 days, and the average amplitude of change per sequence is 0.7 percent of the solar constant of radiation. Corresponding to each individual case of rising and falling sequences, the departures from normal temperatures and barometric pressures were tabulated for a number of widely separated stations; these tabulations ran from 5 days before to 14 (sometimes 20) days after the zeroth day of the sequence. Mean values for successive days were computed (method shown by photographs) for every station and every month, and graphs indicate the average marches of the weather elements attending rise and fall of the solar constant. The main results were: Solar changes affect weather for about 20 days; produce major effects on temperature which are generally opposite for rising and falling solar activity; and may alter temperatures by 10°–15° F. as much as 10 days after the zeroth day, depending on whether the solar radiation has increased or decreased.

These results were confirmed and buttressed by a similar treatment of the observation of calcium flocculi over the sun's disk made at the Observatory of Ebro, Spain, 1910–37; the solar-constant curves and the solar-flocculi curves for temperature departures at Washington, D. C., for all 12 mo. from the day —3 to the day +14 gave a correlation coefficient of 59.7 ± 1.9 percent. It is shown that on the average the weather influence begins 4 days before the solar-constant change begins and 6 days before the areas of solar flocculi are affected. This leads to the hope that some other solar phenomenon may be found that changes simultaneously with the weather effects and is available as a basis for a long-range detailed weather forecast of upward of 2 weeks. Curves are given to illustrate and clarify these and other results. From the combined results of the Smithsonian solar-constant work and the Ebro flocculi photography, solar forecasts were prepared for 201 days of the years 1911, 1915, 1917, and 1935 and compared with the events; the results give fair promise that useful forecasts could be made if daily determinations were available to record all solar changes.

Previously published data show the variation of the monthly means of the solar constant of radiation, its analysis into 14 regular periodicities, and a prediction of solar variation for 1939–45. In the present study the prediction is compared with preliminary monthly mean solar-constant values from Mt. Montezuma, 1939–45; good verification is shown. This led to the expectation of interesting features of weather in 1944, 1945, and 1946; prediction indicated low solar-constant values similar to those of 1922–23 when unusual weather was experienced. Since the period of 273 mo. is the approximate least common multiple of the 14 periodicities in solar variation, and also of the 11⅓-yr. sunspot cycle, weather features should tend to repeat in cycles slightly less than 23 yr. long. Examples are given confirming the 23-yr. cycle in weather features, which has been reduced to a rough rule-of-thumb practice, viz, the mean of the departure from normal temperatures and precipitations of April 46 yr. before, and of February 23 yr. before, indicates the departure for January of the year predicted—and similarly for succeeding months. By employment of this method, useful results for 96 mo. are quoted for Eastport, Me., and for 12 stations scattered over New England; for Eastport 84 mo. out of 96 and for New England 803 out of 1,144 yielded reasonably useful predictions. The individual effects of the 14 periodicities on weather are traced. For shorter periods (8–21 mo.) changes of phase in weather effects of solar variation occur for different seasons of the year.

With seasonal phase changes in weather responses eliminated, it is shown that the period of 8⅛ mo. has been strongly marked at Copenhagen, Vienna, and New Haven since 1800; similar results are in manuscript for other solar periods. Hence it is inferred that in the sun's emission of radiation the 14 periodicities have persisted with unchanged phase for at least 140 yr. The individual effects of the 14 periodicities—and in addition of the sunspot cycle—are computed from records of precipitation at Peoria, Ill., 1856–1929; these are synthesized for 1930–43 and compared to the events. Improvements seem possible by adjusted periods and consideration of terrestrial influences. Attention is drawn to a period of 27.0074 days in Washington precipitation (E. S. R., 91, p. 640); results of comparisons of its indications with the events are given through 1943, and a forecast of days of high precipitation for 1944 is tabulated—with verification for the first 4 mo. of that year excepting April.

Precipitation prospects, 1943–47, for Ohio and near-by States, E. L. MOSELEY (*Mich. Acad. Sci., Arts, and Letters, Papers, 29 (1943), pp. 23–29*).—This is a general discussion of correlations of tree-ring measurements with amounts of annual precipitation and their use as a basis for long-range forecasts of precipitation, with presentation of specific figures for various periods of time and the conclusion that "further data either from tree rings or from unpublished records of rainfall in the middle of the last century may make possible more precise statements regarding probable future rainfall in different areas."

Weather headlines in Ohio, G. W. MINDLING (*Ohio State Univ. Studies, Engin. Ser., Bul. 120 (1944), pp. 124+, illus. 2*).—This compilation of climatological data through 1944 for Ohio—coming from various sources and in some cases going back to the last quarter of the eighteenth century—covers the "head-lines" in cold weather, dry periods, heavy rains, floods, frosts, hailstorms, ice storms, notable snowstorms, nontornadic windstorms, tornadoes, warm weather, and miscellaneous incidents. Tabulated State averages over long periods of years include annual precipitation and snowfall, percentages of normal precipitation by seasons, and temperatures, precipitation, and snowfall by months.

Dommages causés aux plants de tabac par le vent et moyens de les prévenir [Wind damage to tobacco plants and means of preventing it], F. GODBOUT and O. BEAUDOIN (*Quebec Soc. Protect. Plants Rpt., 28 (1936–43), pp. 66–67*).

SOILS—FERTILIZERS

A soil map of Australia, J. A. PRESCOTT (*Austral. Council Sci. and Indus. Res. Bul. 177 (1944), pp. 15+, illus. 1*).—Along with a map of the major soil zones of Australia, this bulletin presents a discussion of the various regions and the environmental conditions prevailing.

Radioactivity of New Zealand soils and rocks, E. MARSDEN and C. WATSON-MUNRO (*New Zeal. Jour. Sci. and Technol., 26 (1944), No. 3, Sect. B, pp. 99–114, illus. 1*).—The alpha ray activities of various soils and rocks in New Zealand, Australia, and Great Britain are reported. The results show that soil radioactivities are dependent upon the rocks from which they are derived rather than the type of soil. Basalts, andesites, rhyolites, and limestones gave low readings, while granites and graywackes gave high readings of alpha ray activities in ionization currents × 10^{18}/cm.^{2}. These results were confirmed in the case of graywackes and basalts by observations with the gamma ray chamber. The gamma ray activity of potassium salts in the samples influenced the results considerably.

A study of the centrifuge moisture equivalent as an index of the hydraulic permeability of saturated soils: A progress report, H. B. ROE and J. K. PARK. (Minn. Expt. Sta.). (*Agr. Engin., 25 (1944), No. 10, pp. 381–385, illus. 5*).—The centrifuge moisture equivalent, M_{eq}, is generally more readily and quickly determined than is the hydraulic permeability (k_s in Darcy's law of fluid flow through porous media, $v = k_s b_f/L$). The authors sought a usable empirical relation between corresponding k_s and M_{eq} values, because numerical values of this coefficient are thus far available for only a negligible number among thousands of soils of differing character, the equipment and knowledge of procedures for making such determinations exist at relatively few places, and the determinations often take considerable time. This study is limited to saturated soils and to tests made on laboratory-prepared samples rather than on undisturbed field samples. A form of variable head permeameter constructed for the direct determination of k_s is described and shown in a diagrammatic drawing and photograph. Derivation of an equation for the computation of the results, from which the final value of the head is eliminated, is shown.

The experimental results showed that there is no mathematical relationship between moisture equivalent and hydraulic permeability sufficiently reliable for direct application to practical problems. There was indicated, however, a general trend sufficiently clear to serve as a guide to the judgment in selecting the probable range of k_s values for a given soil whose moisture equivalent is known, even though the laboratory determination of the exact k_s cannot readily be carried out.

Permeability measurements on disturbed soil samples, M. FIREMAN. (U. S. D. A.). (*Soil Sci., 58 (1944), No. 5, pp. 337–353, illus. 5*).—Some of the factors which influence laboratory permeability measurements are discussed briefly. These are: Method of determination; shape and size of permeameter; water outlet; soil retaining screens; water-head controls; hydraulic gradient; fluids; viscosity; temperature; direction of water flow; entrapped air; texture; volume weight, and water content during packing; effect of sieve size; packing technic; wetting technic; variability of permeability with time; electrolyte concentration; composition of water; and replication.

The author finds that laboratory studies are useful where it is not practical or economically feasible to conduct field trials on soil reclamation and movement of water through soils; and that disturbed soil samples can be used advantageously to study the relative changes in percolation rate brought about by specific chemical and physical soil treatments.

Effect of entrapped air upon the permeability of soils, J. E. CHRISTIANSEN. (U. S. D. A.). (*Soil Sci., 58 (1944), No. 5, pp. 355–365, illus. 6*).—In soils prepared for laboratory permeability determinations and wetted, some air is trapped regardless of whether the water is applied from the top, from below by capillarity, or under a head. Upward flow of water in the permeameter is no assurance of air elimination. Having once become immobilized, this entrapped air can escape only by dissolving in the water. A means of avoiding this air entrapment is to evacuate the dry soil and wet it in the absence of air.

In some soils, the method of wetting under reduced pressure greatly reduces the final permeability obtained. Entrapped air causes a large reduction in permeability compared with that of completely saturated soils. In some instances an increase of more than 30 times the previous minimum rate has been obtained with the elimination of this air. The presence of air in the soil results in permeability values being affected by variations in pressure and temperature. The increase in volume of entrapped air with increase in temperature results in a relative decrease in flow, which partly compensates for the increase in flow due to the decrease in viscosity of the water.

Physical effects of tillage in relation to plant growth (*Alabama Sta. Rpt. 1942, p. 9*).—The effect of soil tillage on plant growth has always been a difficult problem. In an attempt to determine this factor, cotton was planted in 18 experimental plots consisting of various clod mixtures or soil separates ranging in size from less than $\frac{1}{16}$ in. to 2 in. One-half of the plots received an application of surface mulch. Good stands of cotton were obtained on all plots containing clod mixtures that had not been mulched. Where mulch was used the stands were poor. Very poor stands were obtained on both mulched and unmulched plots that contained clod separates of one size only.

Soil crust formation and its relation to crop stand (*Alabama Sta. Rpt. 1942, pp. 7–8*).—Tubs containing Cecil clay loam were planted to cotton, one-half of the tubs being treated with a mixture of sugar and casein to promote bacterial growth in an attempt to find the effect of soil crust formation on crop stands. The treated tubs were found to produce poor stands of cotton and the soils had a hard crust which was very water stable.

Effect of cropping practices on runoff, soil, and fertilizer losses (*Alabama Sta. Rpt. 1942, pp. 9–10*).—The practice of using balks was found to reduce water loss

50 percent and soil loss 17 percent. However, cotton yields from balk plots were only about one-half of those from the check plots.

Stubble mulch farming in southern Idaho, H. C. McKay and W. A. Moss (Coop. U. S. D. A.). (*Idaho Sta. Bul. 256 (1944), pp. 20, illus. 12*).—The effect of straw mulch on erosion, moisture conservation, and yield of wheat under a summer fallow system was determined on a soil corresponding to the Ritzville series at the Tetonia Substation 7 miles northwest of Tetonia, Idaho. The station is located at 6,000-ft. elevation and is characterized by wide seasonal range in temperature and an average annual precipitation of 13.1 in.

Investigations covering a 4-yr. period indicated that burning straw residues is the greatest single factor contributing to erosion of cropland in the southeastern Idaho dry-farm area and that working summer fallow more than is necessary to control weeds has a tendency to increase erosion. For wheat yields and erosion control, surface utilization of straw is superior to mixing it with the surface soil or turning it completely under. Under conditions of heavy straw, burning gave a small increase in yield; but under conditions of light stubble no advantage was gained by burning The burning of stubble in all cases contributed to the erosion problem.

In connection with tillage and the effect of soil-management practices on fertility and erosion, it was found that, after initial tillage, the method of cultivating the fallow giving best results was rod weeding only when necessary. Subsurface implements leave from 90 to 95 percent of the straw and stubble on the surface. The low organic matter and nitrogen content of the surface soil of southern Idaho wheat lands strongly indicates the necessity of not only utilizing all crop residues but also of adopting crop rotations to maintain soil fertility. The success of stubble mulch tillage depends upon the timeliness and quality of operations. All initial tillage and fallow operations should be completed before the weeds and volunteer wheat have made much growth. No subsurface tillage should be undertaken during wet weather. Straw spreaders should be used on all combines.

The bulletin contains general recommendations on practices to be followed in handling crop residues, depending upon the previous yield of wheat obtained.

Contour furrows for water conservation on pasture land (*Alabama Sta. Rpt. 1942, p. 10*).—Three years' results indicated that it does not pay to contour furrow pastures on Norfolk sandy loam, which has a high infiltration rate and good subsurface drainage.

Reclaiming stripped lands in Illinois, L. A. Holmes (*Sci. Mo., 59 (1944), No. 6, pp. 414–420, illus. 7*).—An illustrated article on the extent, appearance, and methods of reclaiming strip mined land of southern Illinois. In 1941, 23,981 acres of land had been mined. It is estimated that the State contains an additional 34,840 acres of shallow coal deposits suitable to recovery by strip mining methods. Through forestation, development of pasture, recreational park areas, and game preserves, the strip mined areas may be used to advantage and will, in the opinion of the author, return a yearly profit to the owner equal to that obtained from the land prior to mining.

The influence of temperature on the microflora of the soil, J. E. Greaves and L. W. Jones. (Utah State Agr. Col.). (*Soil Sci., 58 (1944), No. 5, pp. 377–387, illus. 1*).—Samples of four soils were stored for 24 mo. at 10°, 20°, 30°, and 40° C., and at the end of 6, 12, 18, and 24 mo. were analyzed for numbers of microorganisms, accumulation of ammonia and nitrates, and total gains in nitrogen.

The greatest number of micro-organisms developed on synthetic glucose agar when the soils had been stored at 10°; the fewest after storage at 40°. The accumulation of ammonia was greatest in soils which were stored at 10° and least in those stored at 40°. This difference produced by storage was so great that it was not obliterated by incubating with dried blood for 7 days at 20° or 30°. The storage of soils for 24 mo. at 10° or 20° produced a rather persistent change in their nitrifying microflora. In two out of the four soils stored at 40°, the ability to produce nitrates had been lost. Storage of soils at 20° and 30° for 24 mo. had no significant effect upon their nitrogen-fixing powers, but storage at 40° materially reduced nitrogen fixation. When tested by the tumbler method, storage at 10° was found to reduce greatly the nitrogen-fixing powers of the soils as compared with that of similar soils stored at 20° or 30°.

New Aspergilli from soil, K. B. RAPER and C. THOM. (U. S. D. A.). (*Mycologia, 36 (1944), No. 6, pp. 555–575, illus. 6*).—Five species and one variety of *Aspergillus* isolated from southern or tropical soils are described as new. The new forms are as follows: *A. janus; A. janus brevis; A. caespitosus; A. granulosus; A. panamensis;* and *A. sparsus.*

Correlation between size and number of soil animals, M. S. GHILAROV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 43 (1944), No. 6, pp. 267–269, illus. 1*).—Graphic information is presented on the relation of the size to the number of soil organisms per unit of space. The data suggest a definite regularity in the distribution of the represenative soil fauna over a unit area according to given size groups. The most numerous organisms are the ones of smallest dimensions. The author attributes this size distribution to such factors as food, water, and oxygen supply.

The chemical composition of earthworm casts, H. A. LUNT and H. G. M. JACOBSON. (Conn. [New Haven] Expt. Sta.). (*Soil Sci., 58 (1944), No. 5, pp. 367–375*).—Samples of earthworm casts and of unworked soil from several depths were collected from a cultivated field and from four forested areas and subjected to chemical and mechanical analyses.

At the time of sampling, the field soil contained approximately three casts to the square foot, averaging 2 oz. each, or 16,000 lb. to the acre. In the field soil, casts contained less exchangeable hydrogen and a lower clay content than the 0- to 6-in. layer. The casts had higher pH values and were higher in total and nitrate nitrogen, organic matter, total and exchangeable calcium, exchangeable potassium and magnesium, available phosphorus, base capacity, base saturation, and moisture equivalent. Total magnesium was about equal in all samples. Forest soil samples showed similar, but even more striking, results. Forest soil casts were higher in nitrogen, organic carbon, and exchangeable calcium, and had a higher moisture equivalent than the casts from the field soil.

These changes in composition as the result of earthworm activity are due chiefly to the intimate mixing of plant and animal remains with mineral soil in the digestive tract of the worm and to the action of digestive secretions on the mixture. That earthworms are beneficial to the soil has been established beyond a doubt. Conditions favorable to the worms, however, are at the same time favorable to plant growth, and quantitative measurements under field conditions of the part the worms play in crop production have not as yet been obtained.

Procedures for testing soils: Nomenclature and definitions—standard methods—suggested methods (*Philadelphia 2: Amer. Soc. Testing Materials, 1944, pp. 200+, illus. 96*).—This publication presents 13 American Society for Testing Materials standard methods, as well as 38 suggested procedures for investigating soil and soil mixtures. The compilation consists of the following parts: (1) Indicator tests on soils (pp. 8–58); (2) compaction and consolidation tests on soils (pp. 59–76); (3) strength tests on soils (pp. 77–124); (4) tests for soil-cement (pp. 125–138); and (5) tests for soil-bituminous mixtures (pp. 139–200).

Some modifications in the Neubauer method, W. T. MCGEORGE. (Ariz. Expt. Sta.). (*Soil Sci., 58 (1944), No. 5, pp. 389–397, illus. 2*).—In a study of certain modifications of procedure in the Neubauer seedling test (E. S. R., 53, p. 319), it was shown that both the ratio and the absolute weight and number of seedlings must be maintained at 100: 100, but in availability studies informative data can be obtained by modifying the procedure to use lower weights of soil. The Neubauer test, like the chemical analysis of a soil, is an empirical test because the conditions must be closely adhered to in order to obtain quantitative values. When the Neubauer test is modified by comparing uptake of nutrient elements by rye and by other seedlings the data are confused by lack of uniformity of seed. There is, however, strong evidence that the availability as measured with rye seedlings is applicable to many other crops.

Fertilizer recommendations for Mississippi, 1945, C. DORMAN (*Miss. Farm Res. [Mississippi Sta.], 7 (1944), No. 12, pp. 1, 2*).—The five grades of mixed fertilizers available for 1945 are considered in relation to crop and soil needs for the most efficient wartime production. Fertilizer recommendations are presented for the various soil areas of the State.

Lime and 0–8–6 produce vetch nitrogen for corn and cotton in Brown loam soil areas, H. B. VANDERFORD (*Miss. Farm Res. [Mississippi Sta.], 7 (1944), No. 12, p. 8*).—Grenada silt loam, a Brown loam soil, was used in greenhouse, laboratory, and field studies to determine the most desirable lime level for legume growth. Using soybeans, Korean lespedeza, and sweetclover, it was found that pH 7 was the most desirable level.

Fertilizer practices for cotton on soils of Tallahatchie, J. PITNER (*Miss. Farm Res. [Mississippi Sta.], 7 (1944), No. 12, p. 2*).—Results of soil management studies on Minter fine sandy loam, in the vicinity of Greenwood, Miss., show that increases in yield of seed cotton were obtained by applying commercial fertilizer in addition to growing and turning under vetch. Nitrogen was found to be the fertilizer element most badly needed.

Contribution to the theory and practice of use of nitrogen fertilizers, M. C. ČAJLACHJAN (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 43 (1944), No. 9, pp. 387–390, illus. 2*).—The author discusses the common belief in regard to nitrogen fertilizers causing an increase in vegetative growth and tending to delay the seed-forming processes in plants. It is pointed out that there are certain plants where this may not be the case. Experiments with millet, perilla, lupine, and lettuce, indicate that these plants should be referred to as crops that can be controlled by means of nitrogen application. The use of nitrates is also suggested as advisable in the case of buckwheat, soybeans, and hemp, since increases in yield were obtained without any delay in ripening. It is pointed out that the amount of work thus far completed limits the crops referred to.

Phosphorus investigations, J. L. ANTHONY (*Miss. Farm Res. [Mississippi Sta.], 7 (1944), No. 12, pp. 1, 7, 6*).—The crop response to sources of phosphorus and lime materials is summarized for soils of the hill section of the State. Differences in response are reported for various crops under the different soil conditions.

Phosphates and superphosphate, A. N. GRAY (*London: E. T. Heron & Co., 1944, 2. ed., pp. 416, illus. 38*).—This edition presents a statistical history of the phosphate and superphosphate industries and brings the statistical data up to 1939. The following topics are covered: Phosphates and their uses; production, grades, deposits and reserves, and consumption and trade; superphosphate—origin and history, production, cost of production, consumption, and trade; double superphosphate, calcined phosphates, and phosphate of ammonia; basic slag—production and consumption; and phosphoric acid.

Double superphosphate, A. L. MEHRING (*U. S. Dept. Agr. Cir. 718 (1944), pp. 24, illus. 4*).—The history of the development of the manufacture and of the use of double superphosphate is presented in this circular. In the definition of double superphosphate the author points out that the term "superphosphate" is a general term applied to fertilizer products obtained by treating phosphate rock, apatite, bone, or other phosphatic materials with either sulfuric or phosphoric acid, or with a mixture of both. In order to distinguish superphosphate made by acidulation of phosphates with phosphoric acid from other types of superphosphate, the specific name "double superphosphate" has long been used. In more recent years this material has also been called triple, treble, multiple, and concentrated superphosphate, Electrophos, and other names.

Double superphosphate, as manufactured in 1942, contained 46.5 percent available P_2O_5. Double superphosphate is considered as having the following advantages over other phosphoric materials: (1) For making certain high-analysis mixed fertilizers; (2) for direct use in agriculture in the United States at points distant from a superphosphate plant; (3) in the utilization of certain grades of phosphate rock unsuitable for manufacture of ordinary superphosphate; and (4) in the export market. It is also the ideal material for raising the grade of run-of-pile ordinary superphosphate.

Detailed information is presented on preparation processes, patents, history of production abroad, history of American production, production import and export statistics, uses, consumption, agricultural value, chemical composition, and physical properties.

Changes in pH and in base-exchange properties of cranberry soils following the use of alkaline water, H. H. HULL and N. E. STEVENS. (Univ. Wis. et al.). (*Soil Sci., 58 (1944), No. 5, pp. 405-408*).—Repeated flooding of cranberry soils with alkaline water will increase the base saturation to such an extent that an undesirably high pH value may result. Although under greenhouse conditions this can be brought about in a few years, it will probably take much longer in field practice. Since cranberry marshes are maintained for a long time, however, it appears probable that the regular use of alkaline water for flooding would eventually render them unprofitable for cranberry culture.

The influence of high concentrations of sodium sulfate, sodium chloride, calcium chloride, and magnesium chloride on the growth of guayule in sand culture, C. H. WADLEIGH and H. G. GAUCH. (U. S. D. A.). (*Soil Sci., 58 (1944), No. 5, pp. 399-403, illus. 2*).—Guayule plants were grown in sand culture with a control nutrient solution, and in cultures with this same solution but with 1, 2, and 3 atmospheres osmotic pressure of an added salt (sodium sulfate and sodium, calcium, and magnesium chlorides).

This species was found very sensitive to magnesium, the plants being killed by the lowest concentration of $MgCl_2$ used, but very tolerant of $CaCl_2$, making fairly satisfactory growth in the presence of 3 atm. osmotic pressure of added $CaCl_2$. The plants were relatively sensitive to sodium salts, and at the higher concentrations they were more sensitive to Na_2SO_4 than to NaCl at isosmotic pressures. In the light of these observations, guayule may not be regarded as a salt-tolerant plant.

Inspection of commercial fertilizers, F. W. QUACKENBUSH ET AL. (*Indiana Sta. Cir. 299 (1944), pp. 77, illus. 2*).—This circular presents the usual statistics on fertilizer sales and inspection, including analyses.

Fertilizer inspection, analysis, and use, 1943, M. F. MILLER, L. D. HAIGH, E. W. COWAN, J. H. LONG, and W. A. ALBRECHT (*Missouri Sta. Bul. 480 (1944), pp. 43*).—In addition to the usual analyses and statistics, this bulletin contains timely articles on Wartime Fertilizer Mixtures Approved for Missouri, 1944-45, by L. D. Haigh (pp. 3-4), and Present Observations and the Enlarging Outlook for Fertilizer, by L. D. Haigh and W. A. Albrecht (pp. 5-6).

AGRICULTURAL BOTANY

History and nomenclature of the higher units of classification, L. CROIZAT (*Bul. Torrey Bot. Club, 72 (1945), No. 1, pp. 52-75*).—The author has collected certain notes of interest to the history of botanical thought in general and believed to be even more valuable in elucidating much that is obscure about the origin and nature of systematic units above the genus level. "To be informed about history may rate as an amenity, but to handle these units with purposeful understanding is a necessity." The study consists of two parts: A historical review of the fundamental literature during 1735–89—in which artificial and natural classifications were at last clearly understood and ultimately separated—and additional data for 1789–1905; and a consideration of the issues of practical nomenclature in the units above the genus.

Fisiologia vegetale e piante agrarie [Plant physiology and agricultural crops], R. CIFERRI (*Firenze (Florence): G. Barbèra, 1943, pp. 835+, illus. 300*).—A comprehensive textbook of plant physiology, with bibliography of 13 pages and author and subject indexes.

The outline classification used in the Bergey Manual of Determinative Bacteriology, R. S. BREED, E. G. D. MURRAY, and A. P. HITCHENS. (N. Y. State Expt. Sta. et al.). (*Bact. Rev., 8 (1944), No. 4, pp. 255–260*).—The outline presented has been developed from previous classifications by the editorial board of the manual for use in the sixth edition (in press) of the Bergey Manual. The historical background (24 references) of the work is included.

Routine tests for the descriptive chart: Morphological and biochemical (*Pure Cult. Study Bact., 12 (1944), No. 4, Leaflet 5, 9. ed., pp. 23+, illus. 1*).

Recent advances in our knowledge of the physiology of microörganisms, C. B. VAN NIEL (*Bact. Rev., 8 (1944), No. 4, pp. 225–234*).—A review, with 25 references.

A growth-delaying effect of ultraviolet radiation on bacterial viruses, S. E. LURIA (*Natl. Acad. Sci. Proc., 30 (1944), No. 12, pp. 393–397*).—Ultraviolet radiation, besides inactivating bacterial viruses (bacteriophages), produces a delay in the growth of the surviving virus particles on a sensitive host, this delay becoming longer with increasing doses of radiation. This effect is nonhereditary and more or less strongly marked with different viruses. It is apparently due to the cumulative effect of the quanta absorbed by the virus particles before their inactivation. No similar effect was found on virus particles surviving X-ray irradiation. This is explained by the fact that for ionizing radiation nearly each act of absorption by a virus particle is effective in producing inactivation; the surviving particles are likely not to have absorbed any radiation at all.

Progress in methods of slime control, J. R. SANBORN. (N. Y. State Expt. Sta.). (*Paper Trade Jour., 119 (1944), No. 25, pp. 37–42*).—Investigation of the slime flora prevalent in 340 pulp, paper, and paperboard mills indicated that coliform bacteria were present in 52.6 percent, mold-type fungi in 47.6, and yeastlike organisms in 41.8 percent; and that among the organisms isolated as the principal types, slime-forming fungi and *Aerobacter* spp. were somewhat more prevalent than other groups of micro-organisms. It is concluded that satisfactory control can be obtained only where lethal agents come in direct contact with the living cells; in order to give germicidal agents a chance to work, removal of slime masses is thus necessary. The killing effects of treatments can be considerably increased through use of selected groups of chlorinated phenols employed in suitable combinations of mixtures to produce additive germicidal action. Through use of such procedures, a type of microbiological control can be secured which is not greatly affected by changing conditions, such as seasonal variations.

Studies with Bacillus polymyxa.—III, Nutritional requirements, H. KATZNELSON and A. G. LOCHHEAD (*Canad. Jour. Res., 22 (1944), No. 6, Sect. C, pp. 273–279*).—In further studies (E. S. R., 92, p. 328), 82 strains grew in a medium consisting of inorganic salts, glucose, and casein hydrolysate only when biotin was added. Thiamine stimulated growth of some strains but inhibited others; pantothenic acid, niacin, riboflavin, pyridoxine, and inositol were without effect. Casein hydrolysate was replaceable by urea, $(NH_4)_2SO_4$, and a mixture of 18 amino hydrolyzed acids, but with few exceptions these substances were not as effective as the protein. Asparagine and KNO_3 were poor sources of N. Yeast extract, in a medium containing only glucose and inorganic salts, proved superior in stimulatory effect to all other substances tested.

The seasonal production of agar in Gelidium cartilagineum, a perennial red alga, N. C. Cooper and G. R. Johnstone (*Amer. Jour. Bot., 31 (1944), No. 10, pp. 638–640, illus. 1*).—Two series of 50-gm. samples of the alga—collected at the low tide belt near San Pedro, Calif.—were oven-dried and used in extracting agar to obtain a comparative production for each month of the year. May and June in both series produced more agar than any of the other months; there was a diminution during December-March.

A modification of the method for estimating the anti-bacterial activity of fungi that are difficult to grow on liquid media, W. H. Wilkins and G. C. M. Harris (*Nature [London], 154 (1944), No. 3914, pp. 578–579, illus. 2*).—A modification of the method previously noted (E. S. R., 91, p. 651).

Investigation into the production of bacteriostatic substances by fungi.—Preliminary examination of a fourth 100 species, all Penicillia, W. H. Wilkins and G. C. M. Harris (*Brit. Jour. Expt. Pathol., 25 (1944), No. 5, pp. 135–137*).

Concentration and preservation of crude penicillin, T. T'ung (*Soc. Expt. Biol. and Med. Proc., 54 (1943), No. 1, pp. 103–105, illus. 2*).—The volume of penicillin was greatly reduced, with considerable increase in potency of the active principle, by low vacuum concentration. After an initial drop the titer of concentrated material kept in a dry-ice cabinet was maintained for as long as 6 mo.

A cylinder guide for use in plate assay of penicillin, E. J. Oswald and W. A. Randall (*Science, 101 (1945), No. 2613, pp. 99–100, illus. 1*).—A guide or template is described which facilitates placing the cylinders on the agar surface in the plate assay of penicillin. The general plan of conducting the assay is discussed, and several advantages of the procedure are noted.

Additions to the mycological flora of the Chicago region, J. M. Roberts. (Mich. State Col.). (*Mich. Acad. Sci., Arts, and Letters, Papers, 29 (1943), pp. 51–53*).—In the summer of 1940 the author collected 115 species of agarics in the Chicago area, 43 of which are reported as new to the region and listed. The total of agarics for this area at present is said to be 48 genera, 339 species, and 18 varieties.

More fungi from Florida, W. A. Murrill. (Fla. Expt. Sta.). (*Lloydia, 7 (1944), No. 4, pp. 303–327*).—New species are described under the genera *Clitocybe, Gymnopus, Hydrocybe, Lactaria, Lepiota, Melanoleuca, Monadelphus, Omphalina, Prunulus, Russula, Venenarius, Lepista, Cortinaria, Hebeloma, Naucoria, Agaricus, Coprinus, Stropharia, Ceriomyces, Gyroporus,* and *Ganoderma.*

Rhizophagus in citrus, J. C. Neill (*New Zeal. Jour. Sci. and Technol., 25 (1944), No. 5, Sect. A, pp. 191–201, illus. 7*).—In New Zealand, *Rhizophagus* has been found in the roots of all plant species examined, with the possible exception of exotic pines associated with ectotrophic mycorhizas. *Citrus* spp. have proved susceptible to strains of *Rhizophagus* present in Auckland soils; experimental evidence indicates that it is probably neither harmful nor beneficial to these hosts. The biology of the fungus is briefly discussed.

The genera of Uredinales with citations, G. R. Bisby (*Imp. Mycol. Inst., Mimeog. Pub. 2 (1944), pp. 22+*).—An annotated list of genera of the rust fungi.

Studies upon Galera crispa, E. A. Bessey. (Mich. State Col.). (*Mich. Acad. Sci., Arts, and Letters, Papers, 29 (1943), pp. 9–14, illus. 1*).—Drawing conclusions from the data presented, the author believes that the small mushroom *G. crispa* represents a mutation from *G. lactea.*

Indiana plant distribution records, IV—1943, C. C. Deam et al. (*Ind. Acad. Sci. Proc., 53 (1943), pp. 105–115*).—A continuation (E. S. R., 90, p. 738).

Seasonal growth of twigs of trees in the batture lands of the New Orleans area, J. Bonck and W. T. Penfound (*Ecology, 25 (1944), No. 4, pp. 473–475*).—The data presented are for *Salix nigra*, *S. interior*, *Hicoria pecan*, and *Celtis mississippiensis* during the growing season of 1943.

A revision of Lacmellea and the transfer of Zschokkea (Apocynaceae), J. Monachino (*Lloydia, 7 (1944), No. 4, pp. 275–302*).—A taxonomic study—involving new nomenclature and with a key to the species and varieties—of this latex-producing group of plants, members of which furnish material for crewing gum and rubber.

A contribution to the character of the heterogeneous form of Robinia pseudacacia L. var. monophylla Kirchn., D. N. Beketovskii (Beketovsky) (*Bot. Zhur. S. S. S. R. (Jour. Bot. U. R. S. S.), 29 (1944), No. 1, pp. 29–35; Eng. abs., p. 35*).—This variety of the black locust tree with simple leaves was found to produce only small or medium-sized fruits, which contain a smaller number of seeds. Some of the seeds fail to ripen at all.

Early studies of milkweed utilization in Canada, H. A. Senn (*Canad. Field Nat., 58 (1944), No. 5, pp. 177–180*).—A review of early published reports (five references).

Soil reaction in relation to the distribution of native species, M. H. Stone (*Ecology, 25 (1944), No. 4, pp. 379–386*).—The relation of soil reaction to plant distribution in 25 acres of forest soil in Ohio was analyzed by the chi square technic, using the hypothesis that the plant species occur with the same percentage frequency at every pH value within the soil reaction range of the area; i. e., the species are independent of the pH value of the soil within the pH range investigated. The results obtained indicated that no relationship could be shown between the soil reaction and the distribution of *Acer rubrum*, *A. saccharum*, *Betula lenta*, *Fagus grandifolia*, *Arisaema triphyllum*, *Erythronium americanum*, *Gaultheria procumbens*, *Maianthemum canadense*, *Podophyllum peltatum*, and *Viola hastata*. On the other hand, *Tsuga canadensis* was not independent of the pH value of the soil within the range studied. The distribution of *Claytonia virginica* conformed with the stated assumption when the pH classes were within the observed range of occurrence of the plant. Furthermore, no relationship could be demonstrated between the soil acidity and the distribution of any of the herbaceous species studied if the limits of the pH classes were reduced to coincide with the pH range in which the plant grew most abundantly in the given area. There are 27 references.

Effect of cotton on the germination of Phycomyces spores, W. J. Robbins and M. B. Schmitt (*Bul. Torrey Bot. Club, 72 (1945), No. 1, pp. 76–85, illus. 2*).—A method of studying the germination of spores of *P. blakesleeanus* using 1 cc. of agar medium in spot plates of Pyrex glass is described. Extracts favoring germination were obtained by autoclaving cotton-plugged tubes. The active material was distilled from the cotton plugs by dry steam; it was thermostable, could be concentrated in water solution by evaporation, and disappeared on drying an active solution at 50° or 100° C. unless the solution was neutralized, but was not removed by heating moist or dry cotton at 100°. The material is believed to be an organic acid adsorbed by the cotton and freed by dry steam.

Further observations on the telemorphic effects of certain growth-regulating substances, J. M. Beal (*Bot. Gaz., 106 (1944), No. 2, pp. 165–178, illus. 12*).—In this further study (E. S. R., 91, p. 655), five substituted phenoxy compounds were applied to sweet pea, African marigold, and Red Kidney bean in both Carbowax 1500 and lanolin carriers; indole-3-acetic, α-naphthaleneacetic, and β-naphthoxyacetic acids, tryptophan, and naphthyl acetamide were also applied to the bean in both carriers. The findings indicated that the effectiveness of the carrier depends on the growth substance employed. In these experiments, larger growth responses and form changes resulted, on the whole, when Carbowax was the carrier, though with some substances the responses were essentially equal with both carriers and with 4-chlorophenoxyacetic acid the responses were much greater when lanolin was the carrier.

A comparison of the effect on plant growth of micro-elements and of indole acetic acid and colchicine, T.-L. Loo (*Ann. Bot. [London], n. ser., 8 (1944), No. 32, pp. 356–362*).—The author briefly summarizes the results of a series of experiments on the physiological role of Mn and other trace elements in the growth and development of plants; in these investigations the effects of indole-3-acetic acid and colchicine were usually studied at the same time as those of the trace element.

A simple apparatus for sand culture work, M. E. PADDICK (*Plant Physiol., 19 (1944), No. 4, pp. 704–705, illus. 3*).—The inexpensive device described is particularly suited to set-ups involving substrate materials (such as sand-clay mixtures) through which water movement is slow and in which internal washing effects are difficult to prevent; it is also of value where the use of metal is to be avoided or where the irrigation system should be well enclosed. A glazed culture jar with vertical walls and a drain hole on the side is used as container for the sand; a large Erlenmeyer-type Pyrex glass flask serves as the solution reservoir. Details of construction are illustrated and described.

Effects of isosmotic concentrations of inorganic and organic substrates on entry of water into corn roots, H. E. HAYWARD and W. B. SPURR. (U. S. D. A.). (*Bot. Gaz., 106 (1944), No. 2, pp. 131–139, illus. 3*).—The evidence presented is believed to indicate that the osmotic pressure of the substrate is one of the primary factors in controlling the rate of water entry into the roots. It is also recognized that the character of the solute and the toxicity of salts or ions may have a significant bearing on this function. The conflicting data on the effect of organic substrates are discussed in the light of other work (23 references). The results with inorganic substrates showed that under the conditions employed no significant differences in rate of intake occur when isosmotic pressures of Na_2SO_4, NaCl, or $CaCl_2$ are used as single salts.

Age variations in the absorbing activity of root systems, O. S. SEMENOVA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 43 (1944), No. 8, pp. 354–356, illus. 1*).—On the basis of experiments with *Vicia faba* plants grown in Knop's solution, it is concluded that the mineral absorption rate by the roots decreases with age of plant and that it is largely an active process.

Influence of plant extracts, proteins, and amino acids on the accumulation of selenium in plants, S. F. TRELEASE and S. S. GREENFIELD (*Amer. Jour. Bot., 31 (1944), No. 10, pp. 630–638, illus. 9*).—When young plants of corn and *Astragalus racemosus* were grown in culture solutions containing sodium selenite and organic Se from an aqueuos extract of *A. bisulcatus* at equivalent Se concentrations, both species accumulated far greater amounts of Se from the latter culture solutions. *A. racemosus* exhibited a much greater capacity than corn to accumulate Se from either culture solution; it was also more susceptible to toxic components of the plant extract but less affected by high concentrations of Na_2SeO_3. Though not identified, the Se in the aqueous extract was shown to be present in molecules sufficiently small to diffuse readily through a cellophane membrane; the dialyzed Se had the same toxicity as that in the original extract and was accumulated in the same amount by young corn plants. Extract of nonseleniferous alfalfa hay—added to culture solutions containing Na_2SeO_3—caused an increase in the accumulation of Se by corn plants; specific proteins, protein derivatives, and amino acids—when added to the culture solution for corn—also increased the absorption and storage of Se from Na_2SeO_3. This effect on Se accumulation is said to be one of the few recorded cases in which an organic compound has been shown to increase the absorption of an inorganic element by plants. Though the cultures were not maintained free from micro-organisms, there were no indications that these had any significant influence on the findings reported.

Physiological studies in plant nutrition.—XI, pt. 2; XIV (*Ann. Bot.* [*London*], *n. ser., 8 (1944), No. 32, pp. 323–356, illus. 8; pp. 363–385, illus. 7*).—Two contributions are included:

XI. *The effect on growth of rubidium with low potassium supply, and modification of this effect by other nutrients—pt. 2, The effect on dry-weight distribution, net assimilation rate, tillering, fertility, etc.*, F. J. Richards.—In continuation of earlier studies on barley (E. S. R., 86, p. 305), differences in net assimilation rate were found to account for most of the observed differences in growth under the various treatments used (supplementary nutrients being two P levels in high NH_4-low Ca and in high Ca-NH_4 solutions; a solution of intermediate composition was also used at the high P level). It is suggested that in this experiment the internal P level is one of the dominant factors determining assimilation rate; reduced rates are to be expected when P is either deficient or in excess. The level of P was also a dominant factor in determining the rate of tillering, and early effects of Rb on tillering appear to originate in previous restrictive effects on P uptake; except where P is in excess, Rb reduces early tillering. The final effect of Rb is to increase the number of tillers; this is interpreted as a toxicity effect, resembling Na in this respect. Reduction in the root : top ratio is highly influenced by P; various correlations support the hypothesis that competition occurs between the roots and young tillers for available assimilate, and hence that root size in any treatment depends on the amount of tillering induced by that treatment.

Water contents were increased by raising the P supply and reduced by applying Rb; K supply exerted no consistent effect. The effects of treatments were largest in those groups with highest water contents—interpreted as an effect of carbohydrate level. The ratio of dead to living tops was decreased by raising the K level and much decreased by an equivalent application of Rb—one of the outstanding effects of Rb in this study. The toxicity of excess P and its reduction after adding Rb was sufficient to account for the whole result. Toxicity presumably leads first to a reduction in assimilation rate, then to increased succulence, and finally to death of leaves and tillers. The ear and grain data showed large differences in the Rb effects at the two P levels. Effects of Rb are probably indirect and consequent on previous effects during vegetative phases. There were highly significant correlations of net assimilation rate during the vegetative period with many of the ear and grain data; these appeared to be largely independent of the nutrient conditions causing the observed differences in assimilation rate. Certain possible causes of sterility within the ear are discussed, and it is concluded that grain production and unusually late tillering are competitive processes—if not for carbohydrate, at least for K.

XIV. *Sugar metabolism in the barley stem in relation to ear development*, H. K. Archbold and C. Datta.—In further studies of the sugar metabolism of barley (E. S. R., 88, p. 744), no significant effects of shading the stems and of removing ears or leaves on the fraction of the dry-weight soluble in cold water—other than sugar—were observed. Stems were shaded at 50, 66, and 80 days and leaves or ears removed at 66 days from sowing. Stem shading affected all plant organs; when sugar was still increasing, it restricted both residual dry weight and increase in sugar, but treatment at the time of the sugar maximum failed to induce polysaccharide break-down or to accelerate the rate of sugar loss. In stems and ears, reduction of sugar level was induced by a temporary check in sugar accumulation, from which there was complete recovery within a week, storage being resumed at a normal rate. Relative rates of sugar loss were either reduced slightly or not affected; absolute rates of loss depended primarily on the maximum reached and were low where these maxima were diminished by early treatment.

Defoliation prevented sugar accumulation and restricted residual dry-weight increase, whereas ear removal led to a general increase in sugar level but also tended to inhibit residual dry-weight increase in the stem. Tillers lacking leaves and ears behaved like defoliated tillers, except for maintenance of a slightly higher sugar level. Stem sugars in all treatments reached maxima at the same time and then fell to zero by about 115 days after sowing. The high values reached in earless tillers thus led to rates of sugar loss even greater than in normal tillers, whereas in defoliated tillers, where the maxima were much depressed, rates of loss were low in spite of the depleted carbohydrate supply.

The results of both experiments support the views expressed in earlier papers (1) that free sugars in barley stems are not precursors of starch in the ear, and that their loss from the stem is an inevitable senescent change and not a controlled movement in response to growth demands of the ear; and (2) that major breakdown of polysaccharide does not occur, so that the ear depends on primary assimilate immediately translocated to it or produced in situ. Since shaded or earless stems failed to make normal growth in the presence of increasing amounts of sugar, it appears that utilization of sugar depends mainly on factors other than the carbohydrate supply. The question of the amount of material supplied to the ear by assimilation in the stems is discussed; at present the available results are said to be conflicting.

Plant growth under controlled conditions.—III, Correlation between various physiological processes and growth in the tomato plant, F. W. WENT (*Amer. Jour. Bot., 31 (1944), No. 10, pp. 597–618, illus. 17*).—In the same San Jose Canner tomatoes used to demonstrate the existence of thermoperiodicity (E. S. R., 91, p. 136), a number of physiological processes were studied under the optimum v. suboptimum conditions described. Though the elongation rate of stems decreased sharply during the day, the suction force of the leaves remained essentially constant under constant temperature; only just prior to wilting did a sharp rise occur. The osmotic concentration or pressure of the expressed cell sap was less than half that of the intact cell as measured by plasmolysis or by the suction force at the wilting point. Stomata opened soon after sunrise, remained open during the morning (except with insufficient watering), and closed early in the afternoon. In a dry atmosphere they did not open quite as far and closed somewhat earlier. Darkness, on the other hand, had a much greater effect; when the normal night was artificially lengthened, the stomata opened much less after transfer of plants into the light; temperature had practically no effect on stomatal opening. The changes in stomatal opening were not accompanied by changes in the suction force of the leaf cells. Transpiration changed rapidly with alterations in external conditions—especially light. Considerable fluctuations may occur without measurable changes in stomatal opening; the reverse is also true.

Use of radiophosphorus indicated that phosphate uptake is greater by day and at 26.5° than at 18° C. Bleeding under constant conditions showed a strong periodicity with a maximum around noon and a minimum during the night, its rate depending largely on the sucrose concentration in the root system. A strong negative correlation existed between bleeding and stem growth rate. In carbohydrate determinations, only sucrose values showed a clear correlation with external conditions, its concentration in the leaves rising rapidly during the morning, falling off slightly during the afternoon, and decreasing most at night. In the morning the concentration in leaves of plants kept at 26.5° during the night was significantly higher than in plants kept at 18°–20°. When leaves or stem tips were dried, the amount of auxin which could be extracted with ether increased; during the first hour a large amount was extractable, decreasing in later hours to a steady rate that was kept up for weeks. Auxin production in cut stems and leaves continued for many hours; it first decreased but later increased when cut tips were placed in the dark. The amount of extractable auxin exhibited two daily maxima (morning and afternoon) and two minima (noon and midnight). There was no correlation of day or night temperature or of growth rate with auxin content. Photosynthesis reached its optimum near 1,000 footcandles, was only slightly lower at 18° than at 26.5°, but was significantly lower at 8°. Sugar translocation was small at 26.5°, but steadily increased with lowering of temperature down to 8°. The elongation rate of isolated roots and of the stem by itself was much greater at 26.5° than at 18°.

On the basis of all the evidence gathered, it is concluded that—except just before wilting—the water supply does not limit growth. The hormones considered (auxin, thiamine, caulocaline) are present in sufficient amounts and do not control growth. The light process with an optimum temperature of 26° or higher which controls growth during the day probably is photosynthesis (or perhaps salt intake). The optimum temperature of 18° during the night is caused by a dual control—above 18° the rate of sugar translocation limits growth of stems as well as of roots and fruits; below 18° the rate of the growth process itself becomes limiting. There are 47 references.

Plant fats in relation to environment and evolution, J. B. McNair (*Bot. Rev., 11 (1945), No. 1, pp. 1-59*).—In a search for proper identification of plant groups and their true sequence in evolution, the chemical and physical properties of their fats may be of value. This paper presents a comprehensive review of the literature (120 references) pertaining to this thesis.

The effect of disc thickness on the respiration and the various nitrogen fractions of cut discs of radish roots immersed in water and in sugar solutions, H. Saïd and E. D. H. el Shishiny (*Plant Physiol., 19 (1944), No. 4, pp. 660-670, illus. 4*).—The study involved tissue slices of varied thickness washed in water and then floated on distilled water or sucrose solutions. Respiration and nitrate reduction in the radish slices was increased as their thickness was diminished. Sucrose uptake and protein synthesis were both increased as the thicknesses decreased from 4 to 1 mm.; slices less than 1 mm. in thickness showed no further increase in sugar uptake or protein synthesis. The N fractions playing a major role in protein synthesis in these radish disks of varying thickness were the nitrate and the "other nitrogen." The amide and ammonia N were not significantly affected by variations in disk thickness.

A method for measuring root respiration, D. G. White and N. F. Childers. (Ohio Expt. Sta.). (*Plant Physiol., 19 (1944), No. 4, pp. 699–703, illus. 3*).—By the method described and illustrated in detail, the roots are grown in a medium permitting root and top development similar to that in the field, and the air about the roots can be placed in a closed system so that it is reutilized by the roots for several days while air samples are being withdrawn. Hence the respiratory response of the roots can be determined under conditions similar to those of poor soil aeration in the field, the data can be corrected for respiration of micro-organisms or this can be prevented, the equipment is standard and widely available, and only a few minutes are required to make the daily air analyses.

Spectroscopic stability of chlorophylls a and b and certain analytical considerations, F. P. Zscheile, C. L. Comar, and D. G. Harris. (Purdue Univ.). (*Plant Physiol., 19 (1944), No. 4, pp. 627–637*).—The effects of long-time storage at low temperatures on the absorption curves of chlorophylls *a* and *b* were studied.

Purified preparations of chlorophyll *a* in ether solution were stable for a week or more, after which deterioration was evident; the behavior of dried samples was less predictable. Chlorophyll in crude extracts in ether appeared more stable than in purified preparations. Satisfactory analytical results were obtained on ether extracts from tomato leaves after 14 weeks at —20° C.; storage of fresh corn leaves at 20° for 1 mo. failed to influence analytical results, but chlorophyll deteriorated during longer periods. Storage of leaves in acetone showed some advantages for very long storage periods (7 mo. or more). Small amounts of ethanol, methanol, or acetone in ether solutions and 20 percent water in acetone solutions caused absorption changes; hexane induced no changes in ether solutions. Spectroscopic effects of solvent impurities and of acids are discussed in relation to chorophyll analysis, standards for spectroscopic analysis are considered in relation to stability factors, and comparisons are made from the standpoint of practical application to plant materials. There are 19 references.

Culture conditions and the development of the photosynthetic mechanism.—II, An apparatus for the continuous culture of Chlorella, J. MYERS and L. B. CLARK (*Jour. Gen. Physiol., 28 (1944), No. 2, pp. 103–112, illus. 1*).—The apparatus developed and here described is said to maintain a constant density population of *Chlorella* by automatic dilution of the growing culture with fresh medium. Cells harvested therefrom in daily samples were highly uniform in rates of growth and of photosynthesis measured under arbitrarily chosen conditions.

The growth of Chlorella pyrenoidosa under various culture conditions, J. MYERS (*Plant Physiol., 19 (1944), No. 4, pp. 579–589, illus. 5*).—In this first of a series of papers on culture conditions and the development of the photosynthetic mechanism, the growth of *C. pyrenoidosa* was studied under various culture conditions by means of hemocytometer counts. During the growth of a culture the nitrate and H-ion concentrations were considerably diminished. It was shown on theoretical grounds and experimentally confirmed that the rate of provision of CO_2 may limit growth in such a way as to give rise to a linear growth rate. Higher populations and longer periods of logarithmic growth may be attained by exposing thinner layers of the algal suspension to the incident illumination. The changes in growth conditions within any one culture are manifold, and hence it will be difficult to relate any one of these conditions to effects on the photosynthetic mechanism. There are 17 references.

Light and pigment development in the kidney bean, R. A. WHITMORE (*Plant Physiol., 19 (1944), No. 4, pp. 569–578, illus. 1*).—When red kidney bean seedlings were grown in gravel and tap water under three wavelengths and intensities of light and in darkness, a maximum loss of weight was noted in plants under red light and a minimum under blue light; the weight loss under green light was about equal to that in darkness. Calculation of dry-weight ratios indicated that maximum translocation of reserve material had occurred in plants under red light and that the proportion translocated to the roots was larger than in those under green or blue light; the least translocation was in plants grown in darkness, and the proportion remaining in the region of the hypocotyl and cotyledons was a maximum in these plants. On a fresh-weight basis of the leaves, the maximum amount of chlorophyll and carotene was developed under the green light and the maximum carotenol was developed in darkness and was about equal to that formed under red light. The minimum chlorophyll content was in plants grown under blue light, the minimum carotene under the red, and the minimum carotenol under the blue light. When the total pigment developed by 80 plants in each plot was calculated, the maximum chlorophyll and carotenol was found in plants grown under red light—excluding the dark plot from chlorophyll comparison—and the maximum carotene under green light. The minimum chlorophyll and carotenol was in plants under blue light and the minimum carotene in those in the dark.

Simulation of photoperiodicity by thermoperiodicity, F. W. WENT (*Science, 101 (1945), No. 2613, pp. 97–98*).—It appears from the experimental data presented that the development of tomato plants is not limited by photosynthesis, but that the use of the photosynthates is regulated by processes occurring in darkness at temperatures between 15° and 20° C. This is not true for all plants, since covering beet plants produced only slight and insignificant increase in weight. These studies show that under certain conditions—by proper treatment—the apparent efficiency of photosynthesis can be considerably increased in tomatoes. The effects of covering in these tests were due to thermoperiodicity rather than to photoperiodicity.

Tree foliation affected by street lights, C. A. SCHROEDER. (Univ. Calif.). (*Arborist's News, 10 (1945), No. 1, pp. 1–3, illus. 2*).—"A striking example of prolonged leaf retention in the autumn and subsequent delayed foliation in the spring as the result of supplemental lighting has been observed for several years past in groups of ornamental trees in the cities of Los Angeles and Beverly Hills, Calif."

Effects of controlled shading upon the development of leaf structure in two deciduous tree species, I. T. ISANOGLE (*Ecology, 25 (1944), No. 4, pp. 404–413, illus. 6*).—After exposure of buds in cheesecloth-covered compartments transmitting 70, 48, 22, and 10 percent of full sunlight, respectively, leaf samples of *Cornus florida rubra* and *Acer platanoides* were taken at intervals and studied to compare the effects of differences in light intensity on cell division and elongation in comparison with leaves from the opposite buds exposed to full sunlight. Cell divisions took place in both planes in the development of mature from embryonic leaves in both species, even with the light intensity reduced by 90 percent; all comparable shaded and unshaded mature leaves had the same number of cell layers. Cell divisions increasing the number of cell layers in *Cornus*—from that of the embryonic to that of the mature leaves—occurred before the leaves were 2 cm. long. Since the number of cell layers in shaded and unshaded leaves of each species was the same, differences in light intensity did not affect this process. However, anticlinal cell divisions in the plate meristems responsible for leaf blade expansion in the area were fewer under reduced than under full sunlight. Mature shaded leaves were smaller in area and thinner in cross section than those from opposite unshaded shoots, this difference being due largely to less elongation of the cells in the shaded leaves. All the anatomical differences noted in cross section and most of them in leaf area resulted from variations in cell elongation. Differences in light intensity did not equally affect cell elongation in both planes during development. Light intensity had the greatest influence on elongation of cells in both planes after the leaves were 3 cm. long. There are 36 references.

On the relation between leaf development and formation of lacticiferous vessels in roots of kok-saghyz and krym-saghyz, A. A. NICHIPOROVICH and E. F. IVANITZKAJA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 44 (1944), No. 1, pp. 33–36*).—The lactiferous vessels of kok-saghyz and krym-saghyz are arranged as concentric circles in the bark. It was found that the rhythm of formation of these vessels depends in only a secondary manner on the intensity of leaf formation; the more numerous the leaves produced within the period of intense formation, the better do they influence subsequent thickening of the roots and the consequent development of a larger number of lactiferous vessels therein. The correlations brought out in this study show that a plant should be stimulated to produce at the earliest stage a maximum number of leaves and later on an intense thickening of the root with its lactiferous vessels, and thus to increase the rubber content of the plant.

On the possibility of rubber formation by plants on heterotrophic nutrition

with carbohydrates, A. A. Prokofiev (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 43 (1944), No. 4, pp. 170–173*).—Through experiments with both potted tau-saghyz plants and isolated roots it was found that the formation and accumulation of rubber actually proceeds in the lactiferous vessels of the roots under conditions of heterotrophic nutrition, and that it has no direct relation to photosynthesis and may even proceed without any above-ground parts of the plants available, provided there is a supply of carbohydrates. The hypothesis suggested by others that rubber synthesis takes place in the assimilatory tissues of such plants is considered to be in conflict with the evidence here presented.

Some anatomical effects of moisture stress in nursery seedlings of guayule, F. T. Addicott and J. B. Pankhurst (*Bot. Gaz., 106 (1944), No. 2, pp. 208–214, illus. 6*).—When, under the experimental conditions, sections of root-crown, young stem, and leaf of nursery plants that had been subjected to three levels of moisture stress were examined anatomically, it was found that this factor had no effect on the thickness of the cork, width of the vascular rays or length of cells in the cortex or epidermis, width of cells in the cork or rays, or on the number of cells along a diameter of the pith. Low moisture stress, on the other hand, led to increased cambium activity, resulting in greater xylem and phloem areas with correspondingly longer vascular rays. The diameter of the pith and the size of its cells were also greater under the low moisture stress. At the intermediate moisture stress, xylem development appeared to have priority over that of phloem. High moisture stress led to increased deposition of rubber and lignin and to considerable enlargement of the resin canals. In general, low moisture stress led to enlargement of the tissues of the plant with corresponding increases in rubber-bearing capacity. High moisture stress led to accumlation of the products of photosynthesis.

Toxic substances from the culture media of guayule which may inhibit growth, J. Bonner and A. W. Galston (*Bot. Gaz., 106 (1944), No. 2, pp. 185–198, illus. 1*).—The experiments reported upon show that substances unfavorable to the growth of guayule plants emanate from their actively growing roots; these toxic materials are organic and can be extracted from nutrient solutions which have been previously flushed through gravel cultures of guayule plants. The growth-inhibitory substances contained in nutrient solutions which had been recirculated through guayule cultures proved to be ether-soluble acid compounds; they were not, however, isolated in pure form. A potent source of growth-inhibitory substances was found in water in which guayule roots had been allowed to soak for short periods of time. From such water two inhibitory compounds were isolated in crystalline form, viz, cinnamic acid and an unidentified organic acid.

Growth and heterocyst production in Anabaena cylindrica Lemm., G. E. Fogg (*New Phytol., 43 (1944), No. 2, pp. 164–175, illus. 2*).—During investigations on this nitrogen-fixing alga, observations on the growth of pure cultures shed some light on the nature of the Myxophycean heterocyst; the more important results are described and discussed.

Developmental morphology of vascular plants, H. B. Sifton (*New Phytol., 43 (1944), No. 2, pp. 87–129*).—A comprehensive review (9.5-page bibliography) of the modern science of plant morphology as developed during the past 100 yr. or more.

Algunos casos teratológicos en Gramíneas [Some cases of teratology in the grass family], R. Martínez Crovetto (*Rev. Argentina Agron., 11 (1944), No. 2, pp. 106–115, illus. 7*).

Observations on the presence of stomata in some species of Cuscuta, T. G. Yuncker (*Ind. Acad. Sci. Proc., 53 (1943), pp. 100–104, illus. 1*).—Thirteen species of this parasitic phanerogamic genus are discussed.

The development of the seed of Liriodendron tulipifera L., A. T. Guard. (Purdue Univ.). (*Ind. Acad. Sci. Proc., 53 (1943), pp. 75–77, illus. 4*).

GENETICS

Gene segregation in autotetraploids, T. M. LITTLE (U. S. D. A.). (*Bot. Rev., 11 (1945), No. 1, pp. 60–85*).—In summarizing this comprehensive review (84 references), the author states that three main theories of autotetraploid segregation have been propounded, viz, the Muller hypothesis based on the random assortment of chromosomes at meiosis, that of Haldane based on the random assortment of chromatids, and that of Mather in which the ratios are considered as not fixed but varying according to the amount of quadrivalent formation and the distance of a gene from the centromere. The last is believed most satisfactory in explaining observed data. Though many autotetraploids do not lend themselves readily to genetic analysis, due to sterility, chromosome differentiation, or lack of good genetic characters, fairly extensive studies have been carried out on the autotetraploid genetics of 10 species and genera. The cytological variables affecting autotetraploid segregation are mode of pairing, formation of quadrivalents, and number and position of chiasmata. In progenies unaffected by other variables it is possible to gain an estimate of the position of the gene involved with respect to the centromere. Differential viability markedly affects some of the autotetraploid ratios and can account for some of the discrepancies between observed data and expectancies. Incomplete dominance is more common among tetraploids than among diploids due to the greater number of genotypes possible for any given pair of factors. Because of striking differences between the genetics of diploids and tetraploids, plant breeding procedures applicable to diploids must frequently be modified in dealing therewith.

Mitosis: The movements of chromosomes in cell division, F. SCHRADER (*New York: Columbia Univ. Press, 1944, pp. 110+, illus. 15*).—The larger portion of this volume is taken up with the structure of the cell and its contents and with hypotheses of mitosis—used in the inclusive sense as covering any nuclear division involving a spindle apparatus and the division of chromosomes. Certain related problems are more briefly discussed, and an 18-page bibliography and a subject-author index complete the work.

High fertility of buckwheat tetraploids obtained by means of colchicine treatment, V. V. SACHAROV, S. L. FROLOVA, and V. V. MANSUROVA (*Nature [London], 154 (1944), No. 3915, p. 613*).—A brief note on what is stated to be the first case illustrating high fertility of an experimentally produced, agriculturally valuable autopolyploid form. Of practical importance is the fact that within 2.5 yr. highly fertile buckwheat forms with large seeds were produced, noncrossable with the initial diploid plants.

Inheritance of reaction to smut, stem rust, and crown rust in four oat crosses, G. W. COCHRAN, C. O. JOHNSTON, E. G. HEYNE, and E. D. HANSING. (Kans. Expt. Sta. coop. U. S. D. A.). (*Jour. Agr. Res. [U. S.], 70 (1945), No. 2, pp. 43–61, illus. 4*).—The inheritance of reactions to a mixture of races of *Ustilago avenae* and *U. levis,* races 2 and 8 of *Puccinia graminis avenae,* and race 1 of *P. coronata avenae* was studied in the field and greenhouse in the four crosses, Richland-Fulghum × Fulghum-Victoria and reciprocal, Fultex × Richland-Fulghum, and Anthony-Bond × Richland-Fulghum. In the first three crosses each parent carried a dominant factor for resistance to smut. When these two independently inherited duplicate dominant factors were both absent the plant was susceptible to smut. In the last cross the inheritance was similar except that there was one dominant factor for high resistance to smut and one for moderate resistance. Resistance to stem rust was dominant in all four crosses and appeared to be governed by a single factor. In the three crosses involving the Fulghum-Victoria and Fultex type of resistance to crown rust, resistance was dominant and due to a single factor difference. The crown rust reaction of Anthony-Bond × Richland-Fulghum was controlled by the interaction of four factor pairs—two sets of dominant complementary factors. One set, dominant complementary genes for resistance, was carried by Anthony-Bond (resistant parent), and the other set, dominant complementary inhibitor genes epistatic to the genes for resistance, was carried by Richland-Fulghum (susceptible parent). Observations in F_2 and F_3 proved to be statistically near the expected ratios. No association between the factors determining the reaction to different diseases was noted in any of the crosses studied.

Fertility and sterility relationships among hybrid and specific plum varieties involving eight different Prunus species, W. S. FLORY, JR. (Va. Expt. Sta.). *(Va. Acad. Sci. Proc., 1944, pp. 43–44).*—A summary of work conducted by the author while at the Texas Station presents information on self and cross fertility in a large number of species and varieties of plums. All species used except *P. caroliniana* (2N = 32) had 16 diploid chromosomes. The Methley plum, with a set of 3 percent of fruit upon selfing, was the only one of 15 varieties so tested to produce fruit.

The inheritance of chlorophyll deficiencies in cultivated lettuce, T. W. WHITAKER. (U. S. D. A.). *(Jour. Hered., 35 (1944), No. 10, pp. 317–320, illus. 2).*—Chlorophyll-deficient plants occur sporadically in lettuce fields. The author describes the phenotypic appearance and genetic behavior of four different types of chlorophyll deficiencies. Three cases proved to be cytoplasmic and transmitted by the maternal parent, and the fourth was apparently dependent upon the result of a mutation by a single recessive gene. It is conceded that it is unlikely that either class of chlorophyll deficiency will become a factor in lettuce production, since albino and chlorotic plants are easily eliminated from the seed fields.

Inheritance of bulb color in the onion, A. E. CLARKE, H. A. JONES, and T. M. LITTLE. (U. S. D. A.). *(Genetics, 29 (1944), No. 6, pp. 569–575).*—An analysis of the results of crosses made between a large number of commercial varieties and inbred lines indicated that three pairs of genes are involved in the development of pigments in the onion bulb, namely, a basic color factor, *C-c,* necessary for the production of any pigment; a factor, *R-r,* when the basic color factor, *C-c,* is also present; and an inhibiting factor, *I-i,* which when present in the form of *II* is responsible for the production of white bulbs. In one cross a correlation was noted between color and weight of bulbs, suggesting that the color inhibiting gene, *I,* is linked genetically with one or more growth factors or that this gene is directly responsible for smaller bulb size.

The origin of Lilium testaceum, S. L. EMSWELLER and M. B. STEWART. (U. S. D. A.). *(Jour. Hered., 35 (1944), No. 10, pp. 301–308, illus. 3).*—The chromosome morphology in 5 plants of *L. chalcedonicum,* 16 of *L. candidum,* and 6 of *L. testaceum* was determined from root-tip smears. A high frequency of heteromorphic chromosome pairs was found in *L. chalcedonicum* and some of them also in *L. candidum.* It was possible to assort the latter plants into four groups, each varying from the other three in the number of certain chromosomes present. One type, *L. candidum purpureo-striatum,* had originated following a translocation of the major portion on one arm of the *K* chromosome to the long arm of the *A* chromosome. The chromosomes of *L. testaceum* indicated that it had probably arisen from a cross between one of the types of *L. chalcedonicum* and one of those of *L. candidum* here described.

The inheritance of certain mutant characters in Venturia inaequalis, J. R. SHAY and G. W. KEITT. (Wis. Expt. Sta.). *(Jour. Agr. Res. [U. S.], 70 (1945), No. 2, pp. 31–41, illus. 3).*—Four mutant genes and the sex-reaction factors in *V. inaequalis* were located with reference to their centromeres. All characters studied were found independently inherited except *tan* and *white,* these two genes being located on the same chromosome arm—with *tan* 10.8 and *white* 6.0 cross-over units from the centromere. The effects of a single mutation on the behavior of the fungus may be varied and profound: The *white* mutant prevents development of the characteristic dark pigment in the thallus, induces abortion of ascospores, and probably by interaction with modifying factors suppresses the expression of pathogenicity in the line from which it arose. Another mutant, *small,* is shown to suppress macroscopic expression of pathogenicity, but penetration of the host is accomplished and a microscopic subcuticular development occurs. The importance of adequate attention to modifying factors in parental material before analyzing the inheritance of pathogenicity is emphasized.

Juniperus virginiana, J. horizontalis, and J. scopulorum.—III, Possible hybridization of J. horizontalis and J. scopulorum, N. C. Fassett. (Univ. Wis.). *(Bul. Torrey Bot. Club, 72 (1945), No. 1, pp. 42–46, illus. 4).*—It is shown from further studies (E. S. R., 92, p. 181) that where the two above species occur together there are several things which may happen: Near Sheridan, Wyo., the two occur on opposite sides of the road; *J. scopulorum* there shows tendencies toward *J. horizontalis* in several characters, but the latter exhibits no characters of the former. On the west slopes of the Big Horn Mountains, Wyo., and on the adjacent plains, where no *J. horizontalis* was found, and in the vicinity of Banff, Alberta, where the author has had no opportunity for field studies, there occurs a depressed shrub with the foliage and fruit of *J. scopulorum,* which is described as *J. scopulorum patens* n. var; it is suggested that this variety may have arisen by some ancient hybridization of *J. scopulorum* with *J. horizontalis.*

The improvement of industrial yeasts by selection and hybridization, C. C. Lindegren *(Wallerstein Labs. Commun., 7 (1944), No. 22, pp. 153–168, illus. 7).*—"The improvement of industrial yeasts by hybridization requires an understanding of the life cycle and a consideration of several purely scientific aspects of yeast biology. Among these are factors controlling sporulation, segregation, mutation, and selection. Yeasts exist in both haplophase and diplophase. Hybrids can be produced between haplophases of opposite mating types. Many haplophase cultures are sterile, but when fertile haplophase cultures of different origin are mixed a new hybrid is obtained. The haplophases can be cultured as such but are extremely variable due to mutations which occur during growth. The more stable illegitimate or legitimate diploids are generally used in industrial practice; but if the factors controlling competition between haplophase cells are considered, it is possible to use haplophase cultures for industrial purposes."

Incidence of metabolic changes among virus-resistant mutants of a bacterial strain, E. H. Anderson *(Natl. Acad. Sci Proc., 30 (1944), No. 12, pp. 397–403, illus. 1).*—Virus-resistant mutants were isolated from a virus-sensitive strain of *Escherichia coli* utilizing the selective action of three strains of bacterial viruses (bacteriophages) active on the parent organism. The mutants differed from the original strain in their resistance to either one, any two, or all three viruses, in all possible combinations. Morphological studies and qualitative physiological tests indicated all strains tested to have characteristics similar to the original organism. Of the 57 mutants isolated in pure culture, 28 were unable to grow in a basal medium but grew when 0.005 percent yeast extract was added to the medium. Three representatives were systematically tested with various combinations of 8 vitamins, 23 amino acids, and hydrolyzed casein, none of which—added to the basal medium singly or in combination—would support growth of these strains.

X-ray induced growth factor requirements in bacteria, C. H. Gray and E. L. Tatum *(Natl. Acad. Sci. Proc., 30 (1944), No. 12, pp. 404–410, illus. 5).*—Strains of two species of bacteria were obtained—following X-ray treatment—which were characterized by their inability to carry out specific biochemical reactions. Two strains of *Escherichia coli* differed from the parent strain, one by requiring biotin and the other by requiring threonine. Four mutant strains of *Acetobacter melanogenum* were obtained: The first required a supplement of serine or glycerine; the second, adenine or adenosine; and the third, leucine. With each strain there was little or no growth in the absence of the required substance as contrasted with the excellent growth of the parent strain in the appropriate minimum medium. The growth of each strain was a function of the concentration of the required substance. These results are taken to prove that the capacity of bacteria for carrying out specific biochemical reactions can be modified by X-ray treatment and suggest that biosyntheses in bacteria are controlled by specific genes.

Colonies of Penicillium notatum and other moulds as models for the study of population genetics, G. Pontecorvo and A. R. Gemmell (*Nature* [*London*], *154 (1944), No. 3913, pp. 532–534, illus. 8)*.

Effectiveness of selection on progeny performance as a supplement to earlier culling in livestock, G. E. Dickerson and L. N. Hazel. (U. S. D. A.). (*Jour. Agr. Res.* [*U. S.*], *69 (1944), No. 12, pp. 459–476, illus. 6)*.—Rate of improvement from selection in any closed population, ΔG, is the ratio of the average genetic superiority of parents (compared with the unselected group from which they were chosen), ΔP, to the average generation interval or age of parents when their offspring are born, T. Selection on progeny performance usually follows earlier culling and increases T as well as ΔP. Thus a regular plan of progeny testing is likely to increase the rate of improvement from selection only if (1) progeny performance is obtained early in the tested animal's lifetime, (2) the reproductive rate is low, and (3) earlier selections are relatively inaccurate, as for traits much affected by environment or observable only in relatives. The advisability of progeny testing was examined for representative traits of farm animals. Opportunity for improvement from selection is apparently maximum, or nearly so, for most of these traits when (1) selection on pedigree, individual performance, and family averages is fully utilized and (2) the interval between generations is kept short. The effect of progeny testing on expected progress ranges from a moderate increase for weanling traits of sheep to a definite decrease for growth rate of swine, with a small or doubtful increase for yearling traits of sheep, butterfat production of dairy cattle, and carcass traits of swine.

The hormones regulating reproduction, C. W. Turner. (Univ. Mo.). *(Guernsey Breeders' Jour., 67 (1945), No. 2, pp. 127–132, illus. 5)*.—A popular account of the origin and effects of the hormones concerned with heat, ovulation, and reproduction.

Striping patterns in domestic horses, J. A. Lusis (*Genetica* [*'s Gravenhage*], *23 (1942), No. 1, pp. 31–62, illus. 18)*.—Striping was distributed among very diverse breeds of domestic horses, and it is more distinctly expressed among primitive breeds than among standard breeds, due to continued selection against wild coat colors. In addition to atavistic striping, there occurs in very rare cases striping of a brindling pattern which, like brindling in cattle and dogs, must be regarded as a "new formation" of mutational origin. This study was based on variations in atavistic striping in different breeds of horses throughout the world.

Comparison of growth of Hereford and F_1 [Shorthorn × Hereford] heifers, A. L. Baker and J. R. Quesenberry. (U. S. D. A. coop. Mont. Expt. Sta.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 322–325)*.—In the heifer phase of a crossbreeding project for which the steer phase was previously reported by Phillips et al. (E. S. R., 88, p. 181), comparison of 55 Hereford heifers and 53 F_1 Shorthorn × Hereford heifers from random-selected Hereford cows showed that from growth and weights of the heifers to 30 mo. of age the crossbred calves were significantly heavier at birth, weaning, 18 mo., and 30 mo., and made significantly greater gains to weaning than the Herefords. There was a mean difference of 87.9 lb. at 30 mo.

of age. The score for beef type of the crossbreds was superior to the purebreds at the conclusion of the experiment.

Changes in the physiology and pharmacology of the uterine muscle of the cow in relation to the estrous cycle, P. T. Cupps and S. A. Asdell. (Cornell Univ.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 351–359, illus. 1).*—Studies were made of the motility of the uterine musculature and the size of the cells of the uteri removed from 10 heifers and 1 multiparous cow at various stages of the estrous cycle. Sections of the muscle cells were studied microscopically and the motility ascertained before and after addition of the various drugs by connecting strips of the tissue with a kymograph. The length of isolated muscle cells removed from different parts of the uterus and macerated in nitric acid was ascertained. About 300 cells were measured from each preparation. A few appeared to have two nuclei and a few were split, but only those which were tapered at both ends and contained a nucleus were measured. Spontaneous motility consisted of strong contractions of great amplitude at intervals of 1½–2 min. and small contractions at 20–30-sec. intervals. The latter increased in importance during metestrum. In early diestrum long rhythmic changes of tone also occur. "Pituitrin, arecolin, and lentin produce strong tonic contractions at all stages of the cycle. Eserine, gynergen, and pilocarpine have very irregular effects and are mainly inert. Atropine rarely produces an inhibitory effect. Epinephrin is inhibitory during and shortly after the estrogenic phase, and motor during the progestational phase. The cow thus falls into . . . the 'cat' group in respect to this effect. The muscle cells of the uterus grow in length during the estrogenic phase and decrease in length during the rest of the cycle. The growth impulse starts at the apices of the uterine horns and travels caudally. It is over at the apices earlier than it is in the rest of the tract."

Differences in frequency of cellular antigens in two breeds of dairy cattle, R. D. Owen, C. J. Stormont, and M. R. Irwin. (Univ. Wis. coop. U. S. D. A.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 315–321).*—The frequencies of 30 cellular antigens of cattle as described by Ferguson et al. (E. S. R., 87, p. 854) were determined, 18 of the antigens being significantly more frequent in 569 Guernseys, 5 more frequent in 513 Holsteins, and 7 not significantly different in the two breeds. There was a marked tendency for the percentage frequency of an antigen in one breed to agree with its relative position in the other breed. The two breeds are not distinguished by any single antigen, but the breed differences are mainly quantitative for most of the antigen frequencies. There seems little doubt that the breed differences result from contrasting gene frequencies among genes common to the two breeds. It appears that under selection individuals identical in blood type may be produced by either breed.

The optimum emphasis on dams' records when proving dairy sires, J. L. Lush. (Iowa Expt. Sta.). *(Jour. Dairy Sci., 27 (1944), No. 11, pp. 937–951, illus. 3).*—Nearly all sire indexes yet proposed are special cases of a general class described by the formula $I = a + c\ (X - bY)$, in which X is the average record of the daughters of the sire and Y is the average record of the dams of those daughters, a and c are constants which determine the mean and the variability of a group of indexes, while b determines the relative emphasis on daughters and on their dams. From the principle of multiple regression it is established that, for the index to have maximum accuracy, b should equal the regression of X on Y or be a little less than that regression if the sire's breeding value is correlated with Y. A survey of published data on the regression of X on Y in the actual proof of dairy sires indicates that this optimum value for b is not far from 0.5. Giving this optimum attention to the sire's mates should result in perhaps 15 percent more rapid progress than proving the sires on their daughters' records alone. Adjusting c in the equation will change the variability (and perhaps the convenience) of the index, but not its accuracy for comparing sires with each other.

A new method for indexing dairy bulls, V. A. RICE. (Mass. State Col.). *(Jour. Dairy Sci., 27 (1944), No. 11, pp. 921–936, illus. 1).*—In nearly 50,000 comparisons of dams' and daughters' production in 5 dairy breeds, the individual regression of daughters on dams was of the order of about 0.3 for milk production and 0.45 for butterfat test. Group regression of daughters on dams were of the order 0.5 to 0.6 for both amounts of milk and butterfat tests. The variability of these conditions was reduced about 30 to 50 percent when the data were treated in groups with common environmental conditions as is done in indexing bulls. The "NEW" sire index suggested is based on the sum of the difference between a sire's daughter's actual and normally expected production and the breed average. The formulas for several indexes are presented as follows for comparison:

$$\text{EP (equal parent)} = d + d - m$$
$$\text{Norton} = d + d - e$$
$$\text{NEW} = w + d - e$$

in which d = daughters' production, m = dams' production, e = daughters' expected production, and w = average of the breed. It is the author's opinion that the NEW bull index should be (1) sound from a genetic standpoint, (2) easily arrived at and understandable, (3) calculated in terms of the breed average, (4) comparable in variability to groups of animals rather than to individuals. It should provide a rank of bulls and a definite measuring stick for transmitting performance, a means for predicting future daughters' production, and an accurate means for evaluating pedigrees. It appears that the method makes pedigrees look more nearly like what they are genetically than does the equal-parent method.

Wanted—an improved sire index, V. A. RICE. (Mass. State Col.) *(Holstein-Friesian World, 41 (1944), No. 21, pp. 17, 36, 42, 54–55, 58, illus. 1).*—Essentially noted above.

What the new bull index can do, V. A. RICE. (Mass. State Col.). *(Holstein-Friesian World, 41 (1944), No. 24, pp. 14–15, 63).*—Superiority of the NEW sire indexing method noted above over the equal parent method is pointed out.

'**Horn and scur inheritance in certain breeds of sheep,** H. L. IBSEN. (Kans. Expt. Sta.). *(Amer. Nat., 78 (1944), No. 779, pp. 506–516).*—In discussing the inheritance of horns and scurs in several breeds of sheep, in a continuation of previous studies (E. S. R., 83, p. 756), it is postulated that all sheep are homozygous for the genes for horns. The gene *P* for polled is epistatic to *H*. The gene for horns (*Hm*), a modifier of the above condition, has a different effect in the two sexes, thus a *ppHHhmhm* male is horned and a female hornless. Both sexes are horned when the animal has the dominant form of this modifier. *P* is epistatic to both *Hm* and *hm*. The gene for scurs (*Sc*) is epistatic to *P*, but when heterozygous it expresses itself only in the male. In horned animals *Sc* is hypostatic. Another gene for horns (*Ha*) is epistatic to *P* and hypostatic to *Sc*. A *PpHHScscHaha* male would be scurred, while a *PpHHscscHaha* male would be horned. Another scur gene (*Sr*) was also found in Rambouillet females. A gene (*Su*) permits the horn gene *Ha* to express itself in heterozygous females. Another gene (*Pe*) postpones the expression of *Sc* in males.

Heritability of type in Poland China swine as evaluated by scoring, H. O. HETZER, G. E. DICKERSON, and J. H. ZELLER. (U. S. D. A.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 390–398, illus. 1).*—Study was made of the scores of 731 pigs representing 210 litters sired by 32 boars from 106 sows. The litters were 40 from a small type Poland China strain, 75 from intermediate, 78 from large type, and 17 from crosses between strains. The pigs were farrowed in 14 seasons, but the average scores differed little between seasons. They were scored at 225 lb. live weight in the first 10 seasons, but at the same degree of finish during the last 4 seasons. The small type strain consisted of short-bodied and low-set animals, slow in reaching sexual maturity. The intermediate type tended to have more length of body and well finished at an early age. Pigs of the large type were still longer body and legs. The scores adopted ranged from 1 to 9.

The analysis of variance was used to determine the importance of differences (1) between seasons within strains, (2) between the three types within seasons, (3) between the progenies of sires within the same strain and season, (4) between the litters of the same sires within the same strain and season, and (5) between litter mates. Only the mean squares of differences between litters of the same sire and between full-sib litters were properly to be compared with the intralitter mean square. Differences between sire progenies within strain and seasons fell just short of the 5 percent level of significance. The differences between the litters in the three type strains were highly significant. Calculated variance due to different hereditary and environmental conditions showed that the fraction of variance within strain and season accounted for by heritable differences in the pigs was estimated at 38 percent.

Nonheritable differences among litter mates accounted for 57 percent of the variance, while temporary or permanent differences in litter environment caused only 5 percent of the variance. The heritable fraction of intraseason variance between pigs in different strains was estimated at 92 percent. There was little effect of seasonal differences in environment on the scores—about 4 percent. Differences in type generally existing between small-, intermediate-, and large-type herds of swine are due largely to differences in heredity. The heritability of type is apparently high enough for selection to be effective in changing the type rather rapidly within individual herds. Selections of breeding animals from herds in which type is more extreme in the desired direction makes more rapid progress possible than within the breeder's own herd.

A study of the predictive value of scores on body conformation of pigs taken previous to final score, L. M. Winters and W. W. Green. (Minn. Expt. Sta. coop. U. S. D. A.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 399–405).*—Correlation coefficients were calculated between the scores of 417 gilts when 112 days of age and at 200 lb. in weight or 180 days of age in 5 herds. All were significant at the 1-percent level, and in all except 1 herd there was a considerable margin in the prediction index calculated by methods of Treloar (E. S. R., 84, p. 718), both of which would indicate that a satisfactory job of selection could be done at 112 days of age. The average value of *r* and the prediction index were 0.60 and 0.20, respectively, for the 5 herds. A total of 124 boars was scored in somewhat more detail at 112 days, 140 days, and at the completion of the trial for the animal as a whole, body length, body depth, ham, quality, and feet and legs, in accord with the methods of the U. S. D. A. Regional Swine Breeding Laboratory. Although the correlations were high, the prediction values were so low as to be not at all encouraging. The correlations between the body depth, ham, and total score at 112 and 140 days were over 0.50, but the others were all less at these two ages. Correlations between the other characters at 112 days and when finally recorded were still smaller and the prediction values were disappointingly low.

Preliminary report on crossing of inbred lines of swine, L. M. Winters, P. S. Jordan, R. E. Hodgson, O. M. Kiser, and W. W. Green. (Minn. Expt. Sta. coop. U. S. D. A.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 371–379).*—Crosses within and between breeds showed an increase in vigor in every item of comparison. In 12 of 13 crosses (8 lines within Poland Chinas and 5 between breeds) there was more vigor than the average of the parental lines. There was an increase in vigor of the pigs associated with the decrease in inbreeding. Line crosses between breeds, as measured by fertility, survival, rate of gain, economy of gain, and score for body conformation, were employed in these comparisons. Crosses between breeds were more effective than crosses between lines within the same breeds. An advantage was shown for genetic diversity between stocks. Superior lines seemed to produce superior crossbreds. Crossed lines showed an advantage over crosses of inbreds in the number of pigs weaned, weaning weights, rate of gain, and 180-day weights. The study was based on 249 pigs produced by crossing inbred Poland China lines, 1,105 Poland China inbred pigs, 94 pigs from crosses of different breeds, and 1,509 inbred pigs in 3 breeds.

The relationship between certain blood components and rate of growth in swine, A. W. Nordskog, R. E. Comstock, and L. M. Winters. (Minn. Expt. Sta. coop. U. S. D. A.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 422–430).*—Comparison of the red cell counts, hemoglobin, serum protein, and catalase activity of a total of 45 pigs in 5 inbred lines produced in connection with the U. S. D. A. Regional Swine Breeding Laboratory showed that the level of these blood constituents was higher at 112 days than at 84 days of age. Significant differences were demonstrated between lines for red cell counts and catalase adjusted for hemoglobin concentration. Differences between litters were not significant, but litter differences plus the interaction, age × litters, were significant for all of these blood constituents. In a second experiment, correlation was made at 112 and 168 days of the hemoglobin and serum protein with rate of gain from 56 to 112 days and 114 to 168 days, respectively, for 136 spring pigs in 49 litters from 7 lines. These results showed that growth up to time of sampling was related to the hemoglobin and serum protein, but growth following sampling was not related to these constituents. Gains from 56 to 112 days showed a correlation coefficient of 0.63 with gain from 114 to 168 days. Correlation between the two blood proteins was about 50. Correlation of the blood components was smaller with gains at 114 to 168 days than at 56 to 112 days.

A comparison of the effects of inbreeding and selection on performance in swine, R. E. Comstock and L. M. Winters. (Minn. Expt. Sta. coop. U. S. D. A.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 380–389).*—Study was made of the factors responsible for the merit of inbred lines. In data on 337 litters produced at the Minnesota Station through 1942 (E. S. R., 89, p. 198), the regression of average daily gains on inbreeding was —0.0027 ± 0.0010 lb. There was a decrease of an average of 0.037 pig per litter with each percent increase in the inbreeding of both the dam and the litter. There were considerable errors in these estimates, but the actual results were in substantial agreement with the estimates. Litter size seemed more difficult to maintain in inbred lines than growth rate, which is in agreement with other published results by Hetzer et al. (E. S. R., 84, p. 172). Maximum selection seemed to be necessary for the maintenance of litter size in the development of inbred lines. All factors contributing toward the efficiency of performance are affected by other than genetic factors, as for instance (1) the age of gilt at first farrowing affects first litter size about one-third live pig for 1 month's deviation from 12 mo. of age, (2) pigs out of sows average about 4 lb. heavier than pigs out of gilts throughout the postweaning test period, and (3) feed requirements increase with increased weight at weaning.

A comparative study of epididymal and ejaculated spermatozoa of the boar, J. F. Lasley and R. Bogart. (Mo. Expt. Sta.). *(Jour. Anim. Sci., 3 (1944), No. 4, pp. 360–370, illus. 5).*—The percentage of live sperm removed from the epididymis of 20 boars was studied after 6 and 16 days' storage and compared with the percentage of live sperm in semen ejaculated into an artificial vagina just before castration. Live spermatozoa were determined by the opal blue-eosin technic described by Lasley et al. (E. S. R., 87, p. 500). For storage 1 cc. samples of semen and of suspended spermatozoa were placed in 4-cc. vials, corked tightly, and sealed with paraffin and placed in a beaker containing 300 cc. of water set in a refrigerator at 10°—12° C. The samples were warmed to 35° for testing. Motility was ascertained with low power. At the end of 6 days' storage 75 percent of the epididymal sperm were alive, but only 44.8 percent of normal ejaculated sperm survived to this time. After 16 days' storage 51.2 percent of the epididymal sperm and 9.6 percent of the normally ejaculated sperm survived. An attempt was made to discover the reasons for this difference in viability, and it was found that the chief morphological difference was the presence of a protoplasmic droplet on the midpiece of epididymal spermatoza. Sperm from different parts of the epididymis showed differences in the location of this droplet. The protoplasmic droplet was only on a small part of the ejaculated sperm, and this on the posterior portion of the midpiece. There was only slight motion in spermatozoa from the epididymis, whereas ejaculated sperm were highly motile. Semen added to epididymal sperm increased its motility. Approximately 15 percent of the sperm died in their passage from the epididymis to ejaculated semen. An average of 65 percent of the sperm from the tail of the epididymis survived to 10 min. at 0° as contrasted with survival of only 12.5 percent of sperm in the semen. Sperm showing bent tails were thought to be undeveloped and may result from overuse of the male or disturbance in spermatogenesis.

The prenatal growth of the cat.—XIV, The weight of the skeleton in the fetal and in the adult cat, H. B. Latimer (*Growth, 8 (1944), No. 2, pp. 149–158, illus. 1)*.—Continuing this series (E. S. R., 90, p. 174), the skeleton decreases from its maximum of 18 percent of the body weight in the smallest fetal cat to about 12 percent in the newborn kitten, with a slight increase thereafter.

A case of hermaphroditism in the mouse, E. Fekete and L. B. Newman *(Yale Jour. Biol. and Med., 17 (1944), No. 2, pp. 395–396, illus. 1)*.—On anatomical and histological examination of the genitalia, a mated mouse which had not gotten females pregnant, was found to have both gonads in the abdominal cavity. Microscopic examination of the right gonad showed it to be an ovotestis. The left testis was a typical cryptorchid testis with small, loosely arranged seminiferous tubules. This is said to be the sixth case of hermaphroditism that has been described in the mouse.

Are crossbred chickens really better? R. N. Shoffner (*Minn. Farm and Home Sci. [Minnesota Sta.], 2 (1944), No. 1, pp. 14–15, illus. 1)*.—The progeny of reciprocal crosses between White Leghorn, New Hampshire, and White Plymouth Rock breeds were found to excel purebreds in vigor, as exemplified by about 11 percent in hatchability, laid about 15 more eggs per hen to 500 days of age, and egg production by the crossbreds started at younger ages. The increased vigor makes crossbreds preferred for broiler production, and mortality in the laying flock is reduced to a minimum. Crosses of White Plymouth Rocks and White Leghorns were not much superior to purebreds, and certainly less than crosses between White Leghorns and New Hampshires or White Plymouth Rocks and New Hampshires. In any case, the quality of the crossbred was dependent on the quality of the purebred parent strains, which were usually greater from crossing unrelated stocks. The main disadvantages of crossbreeding are: (1) To produce crossbreeds it is necessary to maintain two purebred flocks; (2) egg color of crossbreds may be objectionable because it is intermediate between the parents; and (3) some crossbreds have an excess of broodiness. Not all crossing is advantageous, but except for eggshell color, crossing of males of the heavy breeds with White Leghorn females was advantageous. Crosses between heavy breeds circumvent the eggshell color problem, but the plumage color may be variable. Considering all factors, crossbreds may not be expected to surpass the very best purebred strains unless the better purebreds are used for the parents.

Studies of genetic viability in the fowl, C. D. Mueller (In *Cornell University Abstracts of Theses, 1943. Ithaca, N. Y.: Cornell Univ. Press, 1944, pp. 287–290)*.—Data on viability, disease resistance, and egg production among 26,609 pedigreed chicks group into families, as previously reported by Hutt et al. (E. S. R., 92, p.

197), are presented in four parts, (1) the consistent performance of sires and dams in different years, (2) the number of daughters necessary to test a sire or a dam, (3) the relation of duration of life in parents to viability of daughters, and (4) viability among adult fowls in relation to viability previous to the age of sexual maturity. A plan for selecting for desired qualities consisted chiefly of obtaining tests of performance of progeny of a large number of pullets and cockerels, viability and egg production of families and close relatives, and duration of life of parents and collateral relatives as a criterion of viability and in selecting families of pullets at housing time.

Methods of breeding chickens for high egg production.—I, Applying the progeny test to a small flock, F. P. Jeffrey *(New Jersey Stas. Bul. 714 (1944), pp. 8)*.—The results in egg production, hatchability, and mortality of selected and unselected lines from 1936 to 1941 showed that by progeny testing with 6 males and 27 female breeders each year over a 6-yr. period, considerable improvement in hatchability of fertile eggs and in egg production was obtained. Of the 34 males tested in the study, only 1 proved to be superior in regard to egg production. However, this sire carried factors for small egg size, and after improving for egg production the line ended with small egg size. More than 6 males must be progeny tested each year to improve the flock in a variety of characters. Laying-house mortality declined from 41 to 13 percent in the unselected line over the 6-yr. period, but only from 29 to 18 percent in the selected line. In the conduct of the work, the selected stock was carried each year with 27 females in laying cages artificially inseminated by the 6 males. The unselected stock consisted of 40 pullets flock-mated with 3 males. The egg production was increased from 84 per year in the selected line and 82 in the unselected line to 164 and 152, respectively. Laying cages were an economical method for progeny testing.

Poultry-breeding-stock selection for desired characters, A. B. Godfrey *(U. S. Dept. Agr. Cir. 715 (1944), pp. 8, illus. 1)*.—Selecting breeding stock on the basis of total score is much more progressive than selecting for a single character at a time. However, selection to independent culling levels permits earlier culling because selection can be made for each character at the time the birds are handled on the range. In selecting on the basis of total score, the characters should be weighed in accordance with their economic importance and their heritability. It is suggested that all breeding birds be graded into three breeding classes, for example, excellent, satisfactory, and poor, on the basis of all characters that can be observed or measured at each of the selection periods. The individual production and brooding records of 25 Single-Comb Rhode Island Red hens are presented.

Effect of hypophysectomy of growing chicks, A. V. Nalbandov and L. E. Card. (Univ. Ill.). *(Jour. Expt. Zool., 94 (1943), No. 3, pp. 387–413, illus. 12)*.—Continuing this study of the effects of hypophysectomy on the growth of chickens (E. S. R., 88, p. 377), 7 of 60 chicks died during or within a few hours after the operation, and 16 were incompletely hypophysectomized. Of the remaining 37 birds, 70 percent died within 1 to 30 days after the operation and 30 percent lived from 31 to 374 days. The normal temperature of hypophysectomized chickens was 41° C., while that of the controls was 42°. The increase in body weight following hypophysectomy was due to the abnormal deposition of fat rather than true growth. The carcasses of pituitaryless chickens contained five to seven times more fat than the controls, and there was a slight increase in length of the long bones. The blood fat (measured as oleic acid of the plasma) was not higher than the blood fat of normal birds. There was possibly an increase in the storage of bile. Study was also made of the histology of the thyroids, adrenals, and other glandular tissues.

Effect of colchicine on mitosis in the neural tube of the forty-eight hour chick embryo, T. M. Woodard, Jr., and S. B. Estes *(Anat. Rec., 90 (1944),* *No. 1, pp. 51–54)*.—Chick embryos of 48 hours' incubation were opened and treated with 1 mg. of colchicine and allowed to continue development up to a maximum of 3 hr. when the average mitotic index was 20.5 percent. Each phase of mitosis except the metaphase declined. The rise in the metaphase is accounted for in terms of the accumulation of nuclei. It is concluded that the concentration of colchicine acts only in this way and is not a mitotic stimulant.

Studies in the genetics of Drosophila, II, III, directed by J. T. PATTERSON *(Tex. Univ. Pubs. 4228 (1942), pp. 200, illus. 46; 4313 (1943), pp. 327, illus. 170)*.—Two further contributions (E. S. R., 87, p. 363) are included.

II. *Gene variation and evolution*.—This installment contains the following papers: Inter-specific Hybridization in the Genus *Drosophila*, by J. T. Patterson (pp. 7–15); Heterosis in *Drosophila hydei*, by W. S. Stone (pp. 16–22); Analysis of the *repleta* Group of *Drosophila*, by L. T. Wharton (pp. 23–52); Cross Fertility and Isolating Mechanisms in the *Drosophila mulleri* Group, by J. F. Crow (pp. 53–67); Relationships in the *melanica* Species Group, by A. B, Griffen (pp. 68–73); Genetic Relationships in the *Drosophila funebris* Group, by G. B. Mainland (pp. 74–112); A Study of Intersexes Produced by a Dominant Mutation in *Drosophila virilis*, Blanco Stock, by W. W. Newby (pp. 113-145); The Ix^B Factor and Sex Determination, by W. S. Stone (pp. 146-152); Distribution of the *virilis* Group in the United States, by J. T. Patterson (pp. 153-161); and Genetic and Cytological Analysis of the *virilis* Species Group, by J. T. Patterson, W. S. Stone, and A. B. Griffen (pp. 162-200).

III. *The Drosophilidae of the Southwest*.—Herein are brought together the more important facts on the various species of *Drosophila* known to occur in the southwestern United States and northern Mexico. The "Southwest" here used includes the area embracing the States of Texas, Oklahoma, New Mexico, Colorado, Arizona, Utah, Nevada, and California and the Mexican States of Tamaulipas, Nuevo Leon, Coahuila, Chihuahua, Sonora, and Baja California. The following papers—including new taxonomy—make up this volume: The Drosophilidae of the Southwest, by J. T. Patterson (pp. 7–216); Geographical Distribution of Species of the Genus *Drosophila* in the United States and Mexico, by J. T. Patterson and R. P. Wagner (pp. 217–218); and Analysis of the Metaphase and Salivary Chromosome Morphology Within the Genus *Drosophila*, by L. T. Wharton (pp. 282–319). A subject index is provided.

FIELD CROPS

[Field crops research] *(Jour. Amer. Soc. Agron., 36 (1944), No. 12, pp. 988–995, 995–1003, 1014–1015, 1016–1017, 1019–1020, 1021–1023, 1024)*.—Papers concerned with different phases of field crops investigations, which were to have been presented at the annual meetings of the American Society of Agronomy and the Soil Science of America in 1944, and published in abstract form in these pages included: Gamete Selection in Corn Breeding, by L. J. Stadler (pp. 988–989) (U. S. D. A.); Recurrent Selection for Specific Combining Ability in Corn, by F. H. Hull (pp. 989–990) (Fla. Expt. Sta.); The Value of Self-compatibility in Breeding White Clover, by S. S. Atwood (p. 990) (Cornell Univ.); Intra-varietal Crossing in Wheat, by J. B. Harrington (pp. 990–991); Inheritance and Interaction of Genes Governing Reaction to Stem Rust, Leaf Rust, and Powdery Mildew in a Spring Wheat Cross, by D. G. Wells and S. P. Swenson (pp. 991–992) (Wash. State Col.); Nitrogen Fertilization of Bermuda Grass Pastures, by O. E. Sell (p. 992) (Ga. Sta.); The Improvement of Carpet Grass Pastures by Fertilization and Seeding to Clover, by E. L. Mayton (p. 993) (Ala. Sta.); Some Factors Affecting Pasture Production in Western North Carolina, by W. W. Woodhouse, Jr. (p. 993) (N. C. Sta.); Some Experiences in Revegetating Poor Hill Land Pastures in West Virginia, by R. M. Smith, G. G.

Pohlman, F. W. Schaller, and D. R. Browning (p. 994) (Univ. W. Va.); Critical Phosphorus and Potassium Levels in Ladino Clover Plants, by A. Ulrich (p. 994) (Univ. Calif.); Grass-Legume Hay Response to Various Fertilizer Ratios, by A. Rich and B. E. Gilbert (pp. 994–995) (R. I. State Col.); Agronomy, a Phase of Military Engineering, by R. H. Morrish (pp. 995–996); Yields From Single-Plant Hills vs. Multiple-Plant Hills at the Same Population of Corn Plants Per Acre, by G. H. Dungan (p. 996) (Univ. Ill.); Alfalfa and Grass Percentage Determinations With the Inclined Point Quadrat Apparatus at Different Stages of Development of the Mixtures, by A. C. Arny (pp. 996–998) and The Development of a Synthetic Variety of Corn From Inbred Lines, by H. K. Hayes, E. H. Rinke, and Y. S. Tsiang (pp. 998–1000) (both Univ. Minn.); Winter Injury and Persistence in Alfalfa, by F. R. Jones (p. 1000) and Some Problems in Testing Selected Strains of Forage Plants in Pasture Trials, by H. L. Ahlgren (pp. 1000-1001) (both Univ. Wis.); A Selection Experiment with Kentucky Bluegrass, by H. K. Hayes and H. L. Thomas (pp. 1001–1002) (Univ. Minn.); Methods of Evaluation of Red Clover Strains Grown Alone and With Timothy in Small Plots, by J. H. Torrie and J. L. Allison (pp. 1002–1003) (Wis. Sta.); Evaluation of Strains of Kentucky Bluegrass in Association With White Clover, by W. M. Myers and V. G. Sprague (p. 1003) (U. S. D. A.); The Nature of the Flora on Field-retting Hemp, by W. H. Fuller and A. G. Norman (p. 1014–1015) and Comparative Effects of Plowing and Other Methods of Seedbed Preparation on Nutrient Element Deficiencies in Corn, by C. A. Bower, G. M. Browning, and R. A. [Farm crops research in Mississippi] (*Miss. Farm Res.* [*Mississippi Sta.*], *7 (1944), Nos. 11, p. 8; 12, pp. 4, 5, illus. 1).*—Progress of experiments with field crops and related research is reported in the following articles: No. 11, Fertilization the Most Important Pasture Practice, by H. W. Bennett (p. 8); No. 12, A Study of the Cotton Root System, by O. A. Leonard (p. 4); Winter Legumes and Fertilizer for Cotton Production, by J. Pitner (p. 4); and Liming Increases the Yield of Seed Cotton in Test on an Upland Brown Loam Soil, by C. D. Hoover (p. 5).

[Field crops theses] (In *Cornell University Abstracts of Theses, 1943, Ithaca, N. Y.: Cornell Univ. Press, 1944, pp. 330–332, 403–405, 411–414).*—Abstracts are given for theses entitled: Quantitative and Qualitative Inheritance in Barley, by S. Dasananda; Birdsfoot Trefoil (*Lotus corniculatus*), by H. A. MacDonald; and Effect of Competition on Emergency Forage Crop Technic, by D. L. Van Horn.

Field crops of India, with special reference to Mysore, A. K. YEGNA NARAYAN AIYER *(Bangalore: Govt. Press, 1944, pp. 552+, illus. 79).*—Practical information on fields crops of importance in India is presented in chapters covering distribution, soils, rotations, cultural and harvesting practices (mainly those prevalent in Mysore), yields, botany and varieties, pests and diseases, chemical composition, and production and trade, and grouped in sections dealing with grains; legumes; oil seeds; sugarcane; food crops (bananas, potatoes, tapioca); condiments and spices; fiber crops; tobacco, coffee, tea, and narcotics; medicinals; dyes; and special products (mulberry and silk, and Para rubber). An index is included, together with a glossary, and appendixes on manures and fertilizers and insecticides and fungicides.

A study of the reliability of range vegetation estimates, A. D. SMITH. (Utah Expt. Sta.). *(Ecology, 25 (1944), No. 4, pp. 441–448).*—The accuracy and extent of variation between individual estimates of vegetation density and the effect of a training period on the uniformity of estimates were studied in 1939 on ungrazed sagebrush, winterfat, and grass vegetation types by a crew of eight men. Density estimates were not shown to be a highly reliable measure of range value since "high" estimators found ranges to have almost twice the grazing capacity found by "low" estimators, even after a week of intensive training. A significant difference was found between individuals and also a given individual had significant inter- and intradaily variation. Plants showed great variations in yield from a unit of density both within and between species. The results supported the current tendency among range technicians to rely less upon density estimation as a means of determining grazing capacity of ranges, and more upon comparison with ranges of known productivity and a general ecological analysis of plants and soil followed by percentage adjustments in current stocking.

Reseed range land to increase grazing capacity and produce more beef per acre, C. H. WASSER *(Colo. Farm Bul. [Colorado Sta.], 6 (1944), No. 5, pp. 12–14, illus. 2).*—Adapted species and mixtures of grasses and legumes listed for reseeding range on the plains, lower mountainous and foothill plains, and the mountainous region, and the dates, rates, and methods of seeding indicated are based on results of station experiments in different localities in Colorado.

Better pastures for dairy cattle, W. B. NEVENS *(Illinois Sta. Bul. 505 (1944), pp. 227–271+, illus. 34).*—Pasture experiments 1935–42 were made to develop a system which would supply ample forage in midsummer, to evaluate certain legumes and grasses and a mixture for pastures, and to increase the yield and protein content of Kentucky bluegrass.

Bluegrass usually has not been satisfactory in central Illinois for use as the only pasture crop because of low yields and low feeding value during midsummer. These faults could be overcome somewhat by good management practices as fertilizing heavily, beginning grazing only after good growth of grass, removing cattle early in autumn, and removing large perennial weeds. More and better forage could be obtained more effectively from the same area of pastureland, by use of several crops, as winter rye, bluegrass, alfalfa, a Sudan-soybean mixture, bromegrass, and sweetclover—in rotation. The mixture has made high-yielding and drought-enduring midsummer pasture. Winter rye has been ready for grazing 1 to 2 weeks earlier than bluegrass, and bromegrass several days earlier. In seasons of low rainfall, the rotational system provides pasture longer than bluegrass.

Pasture planted first to winter rye and then to a Sudan grass-soybean mixture usually has yielded much higher than pasture planted to one crop only, but the forage supply has not been continuous. While both have outyielded bluegrass, alfalfa needs reseeding oftener and bromegrass recovers more slowly from close grazing. Pasture crops evidently should be rated on feeding value, palatability, economy of production, timeliness of yield, length of pasture season, resistance to drought, weeds, and tramping, likelihood of causing bloat or other upsets, and adaptability to soil and climate, as well as on total yield.

Fertilizing with urine, in addition to manure, has increased yield, protein content, and palatability of bluegrass. Urine-treated grass has had a consistently lower dry-matter content than untreated. A close relation between low dry-matter content (high moisture content) and palatability was apparent. As bluegrass, bromegrass, and winter rye have developed, their dry-matter, lignin, and cellulose contents have risen. At the same time, protein content gradually has declined until the forage contains only about half as much as at the beginning of the season. Bromegrass, winter rye, and the Sudan-soybean mixture made good pastures because of low weed content and high yields. The weed content of bluegrass pastures did not decline despite good management for 8 yr.

Improving bluegrass pastures, W. B. NEVENS (*Illinois Sta. Bul. 504 (1944), pp. 215–224+, illus. 3*).—Kentucky bluegrass pasture plats variously treated, disked, and manured were harvested by mowing weekly or every 2 weeks, and an untreated plat twice a year 1909–13. Bluegrass harvested weekly had a slightly higher percentage of protein than that mowed biweekly and a slightly smaller annual yield of dry matter, but the total amount of protein did not differ significantly. Double disking once in the spring increased the yearly yield of dry matter considerably, increased the percentage of protein to a small extent, but did not change the total amount of protein significantly. Application of manure more than doubled the yearly yield of dry matter, increased the protein percentage in the dry matter by one-sixth, and nearly trebled the total amount of protein. Yields declined when grass was harvested over a period without return of fertility to the soil.

Manure is best pasture improver, D. M. SEATH and L. L. RUSOFF (*Dairy Res. Digest* [*Louisiana Sta.*], *2 (1944), No. 4, p. 1*).—Pasture experiments in three parishes over 3 yr. demonstrated the merits of manure either in establishing new pasture or renovating an old one. Definite improvement in stands of clovers and grasses followed application of manure + P or + Ca PK.

Fertilizing to increase the yield and longevity of alfalfa in Georgia, L. C. OLSON (*Amer. Fert., 101 (1944), No. 11, pp. 28, 30*).—Fertilizer tests by the Georgia Experiment Station, 1942–43, indicated that lack of potash is one of the principal reasons why alfalfa stands cannot be maintained. Cultural and fertilizer practices are outlined.

The alfalfa seed production problem. (Coop. U. S. D. A.). (*Farm and Home Sci.* [*Utah Sta.*], *5 (1944), No. 4, p. 3, illus. 3*).—Since alfalfa flowers must be tripped to obtain a good seed set and the tripping agents found in Utah alfalfa are honeybees and wild bees which nest in or on the ground, seed growers are encouraged to keep honeybees near alfalfa fields and to protect nesting places of wild bees and apply insecticides carefully. Cutting weeds lessen the competition for pollen-collecting insects. Regulation of irrigation practices to avoid rank growing succulent alfalfa may reduce injury from lygus bugs. The foregoing practices are based on findings by J. W. Carlson, C. J. Sorenson, et al.

Mars—A new high-yielding barley for Minnesota growers, M. T. HENDERSON and J. J. CHRISTENSEN (*Minn. Farm and Home Sci.* [*Minnesota Sta.*], *2 (1944), No. 1, pp. 4, 12, illus. 1*).—Mars barley, a productive early, six-rowed, smooth-awned variety introduced in 1944, has very strong straw with a record of less than one-fourth as much lodging as in Wisconsin Pedigree 38 and averages 3 to 4 lb. per bushel heavier. It is resistant to stem rust and moderately resistant to spot blotch, but is susceptible to scab and loose smut. Because of low diastatic power, it may not be entirely satisfactory for malting. Mars was produced in cooperation with the U. S. Department of Agriculture et al. from a cross made in 1931 between Minnesota 462 and Peatland barleys. Seed was not expected to be available for general distribution until 1946.

Canaigre investigations, I, II. (U. S. D. A. and Tex. Expt. Sta.). (*Jour. Amer. Leather Chem. Assoc., 39 (1944), No. 12, pp. 467–479, illus. 2; pp. 479–491, illus. 5*).—Two papers of the series are presented.

I. *A review and preliminary report,* J. S. Rogers and G. A. Russell.—Samples of wild roots of canaigre collected from 12 locations in four Southwestern States ranged in tannin content from 9.0 to 32.1 percent. In 25 samples collected near Las Cruces, New Mex., tannin ranged from 11.2 to 35.3 percent and total sugars from 8.1 to 19.6 percent. Tannin contents of roots of the same age and from the same hill varied as much as 3.1 percent, significantly less than variation of averages representing different hills. Analyses of bodies of roots could be used to determine whether corresponding crown portions, taken for planting, represent high-, medium-, or low-tannin strains. The program for cooperative investigation of canaigre (*Rumex hymenosepalus*) as a source of tannin is outlined, and the early history of canaigre is briefly reviewed. The plant and roots are described, and its habitat is given.

II. *Dehydration of bulk lots of canaigre roots in the locality where harvested*, G. A. Russell, J. S. Rogers, and E. C. Stevenson.—Canaigre roots could be shredded at Sacaton, Ariz., at the rate of 1 ton per hour with a shredder built in accordance with specifications of Kummer (E. S. R., 88, p. 258; 89, p. 733). Shredded roots were dried satisfactorily in the sun on asphalt and concrete in 24 hr. under climatic conditions prevailing in June 1943, when spread at the rate of 1.25 lb. per square foot. Under such conditions 1 acre of drying surface would handle 20 tons of freshly shredded roots and yield about 5.5 tons of air-dry material per day. Drying finely ground or partially pulped roots spread at rates of 10 and 5 lb. per square foot of drying floor resulted in fermentation and destruction of tannin and sugars. Satisfactory color skivers were obtained by using water extracts from the dried shredded roots.

Inheritance of strength of lint in upland cotton, J. O. Ware and D. C. Harrell. (U. S. D. A. coop. S. C. Expt. Sta.). *(Jour. Amer. Soc. Agron., 36 (1944), No. 12, pp. 976–987).*—Parental lines were grown along with F_1, F_2, and F_3, first-generation backcrosses, and second-generation backcrosses from a Florida Green Seed (E. S. R., 90, p. 31) and Rowden cotton cross for comparisons and for use in recrossing and in the backcrossing. The F_1 was repeated in the second and third years. The first backcross was made with F_1 in 1939 to both parental lines. In 1940, plants in the respective first-generation backcrosses were backcrossed again to corresponding recurrent parental plants. Florida Green Seed stock had the higher strength index, which was about 1 unit higher than in Rowden as determined by use of the Pressley strength tester. Inheritance of strength appeared to be intermediate with slight tendency to weak dominance; in repeated backcrossing the level of strength is easily shifted in either direction. Strength in F_3 progenies from plants selected out of the several F_2 class intervals did not exhibit as much uniformity as shown by either parent, but these F_3 plants tended to maintain the F_2 level of origin. In 1939 and 1941 the respective parental lines were at about the same level, but higher in 1940. In several hybrid groups the 1941 level was lower than the 1940 level. Environment was a factor and doubtless contributed to expression of variability and in changing season mean levels, yet the yearly combination or set-up permitted reliable genetic measures.

The uptake of nutrients by the cotton plant when fertilized with acid forming and non-acid forming fertilizers combined with different rates of potash, J. J. Skinner, J. G. Futral, and N. McKaig, Jr. (Coop. U. S. D. A.). *(Georgia Sta. Bul. 235 (1944), pp. 21, illus. 7).*—Profitable increases in yields of seed cotton have been produced by neutralizing the fertilizer with dolomitic limestone on most of the principal soil types of the southeastern Cotton Belt, including some soils in Georgia (E. S. R., 88, p. 739). Neutralizing the fertilizer has not materially affected the crop's requirement for K, for cotton made essentially the same yield increase regardless of the K content of the fertilizer.

The lower N percentage in Deltapine cotton plants on Clarksville gravelly loam grown with non-acid-forming fertilizers than in plants grown with acid-forming fertilizers differs from results on Tifton sandy loam, being due perhaps to differences in response to dolomitic limestone on the two soils and to the character of the soil. Fertilizers neutralized with dolomitic limestone, in general, did not materially change the composition of cotton plants (E. S. R., 88, p. 760) as compared with plants grown with acid-forming fertilizers, except in Mg content. Early availability to cotton of Mg in dolomitic limestone is indicated by the larger amount of Mg in the plants in early growth, and throughout the growing period. In addition to the N, P, and K taken up by cotton plants, large amounts of Ca and appreciable amounts of Mg were absorbed. The larger plants with increased yields produced by non-acid-forming fertilizers contained larger amounts of nutrients per plant. Cotton fertilized with such fertilizer made larger and earlier growth and absorbed more nutrients per plant early in the season than plants receiving an acid-forming fertilizer, suggesting that the limestone in fertilizers makes the nutrients more readily available.

Increasing amounts of applied K (0, 3, 6, and 9 percent K_2O) increased the K percentage in the plant and reduced the Mg percentage at all growth stages. There were consistent but small decreases in the percentages of N, Ca, and P in the plant as K applications increased, although the total amount of all nutrients per plant rose with the amount of K applied. The effect on plant composition of K was greater than that of dolomitic limestone in fertilizers with exception of the greater Mg content from dolomitic limestone. Increased rates of applied K were accompanied by increased uptake per plant of K and an increased uptake per plant of other nutrients.

Winter hardiness in guayule, J. W. Mitchell. (U. S. D. A.). *(Bot. Gaz., 106 (1944), No. 1, pp. 95–102).*—Woody outdoor seedlings of guayule not yet unacclimated to low temperatures survived temperatures only slightly lower than did very succulent greenhouse plants of the same age. Rate of cooling preceding extended exposure to low temperatures did not alter appreciably resistance to frost injury. Unhardened seedlings of four varieties withstood prolonged exposure to a temperature of 25° F. but were severely injured after 8–10-hr. exposure to 22°. Roots usually were injured severely by prolonged exposure to soil temperatures of 26°–28°. Stems and leaves of transplants were acclimated readily by low temperature hardening treatments, so that they withstood repeated exposure to 5°–10°. Stems of hardened plants of selection A-5058 (found most resistant to frost injury) withstood 3-hr. exposure to 5°. Their roots were slightly injured, but the plants survived. Experimental field plantings may readily be protected from temperatures 4° and probably lower by an adequate mulch. Rubber content of plants injured severely by frost did not differ significantly from that of comparable uninjured plants during 1–2 mo. after treatment.

The influence of depth of surface soil on potato yields, O. R. Neal. (N. J. Expt. Stas.). *(N. J. State Potato Assoc., Hints to Potato Growers, 25 (1944), No. 8, pp. [2–3, 4]).*—During 1944, potatoes made an average total yield of 184 bu. per acre on 25 farms from areas with more than 6 in. of surface soil remaining in place. Areas on the same farms having less than 6 in. of surface soil yielded 135 bu. Yield from all slightly eroded areas measured 1941–44 averaged 48 bu. per acre, 25 percent greater than that from seriously eroded areas. The value of erosion control for a long-time maintenance of soil productivity was clearly indicated.

Potato fertilization and nutrition studies in 1943, O. Smith. (Cornell Univ.). *(Amer. Potato Jour., 21 (1944), No. 12, pp. 342–355).*—Results of investigations published largely in 1943 and early in 1944, concerned with fertilizers, practices and replacements, soil amendments, and minor elements for the potato and effects of fertilizers on vitamin content, cooking quality, and diseases of potatoes are summarized, with a list of 55 titles.

Dormancy, bud growth, and apical dominance regulated by oxygen in freshly-harvested potato tubers, N. C. THORNTON (*Contrib. Boyce Thompson Inst., 13 (1944), No. 8, pp. 361–366, illus. 1*).—The dormancy of freshly harvested Irish Cobbler and Bliss Triumph potatoes was broken and bud growth obtained within 7–9 days by continuous treatment of the tubers with 2 percent of O_2 in relatively dry condition or 5–10 percent in most condition at 23°–28° C. Bud growth was produced on tubers stored in pure nitrogen for 18 days following harvest. These treatments caused the elimination of apical dominance of the buds in the apex eyes of the tuber over those in eyes at the basal or stem end; they also removed the controlling effect of the apical bud over the lateral buds of each eye so that many buds developed in every eye of the freshly harvested potato. When potatoes removed from the treatments were cut into one-eye pieces and planted in soil, vigorous multiple plants were produced from the one-eye pieces that had been exposed to reduced percentages of O_2.

Place and season effects on yields and starch content of 38 kinds of sweetpotatoes, V. R. BOSWELL, M. T. DEONIER, R. L. CAROLUS, J. B. EDMOND, O. B. GARRISON, H. L. COCHRAN, O. WOODARD, W. S. ANDERSON, J. C. MILLER, and R. E. WRIGHT. (Coop. Ga., La., Miss., S. C., Tex., Ga. Coastal Plain, and Va. Truck Expt. Stas.). (*U. S. Dept. Agr. Cir. 714 (1944), pp. 15*).—Acre yields of sweetpotatoes, starch content, and yield of starch per acre were determined 1940–42 from uniform tests in Maryland, Virginia, South Carolina, Georgia, Mississippi, Louisiana, and Texas. Tests at Onley, Virginia, were made on wilt-infested soil primarily to determine varietal reactions to wilt. See an earlier note (E. S. R., 88, p. 189).

Location and seasonal conditions at any one place have had marked effects on sweetpotatoes in the percentage of starch, total yields, and the commercial grades of roots produced. Whenever drought was serious enough to reduce greatly the yields of sweetpotato roots per acre, the percentages of starch and of total dry matter in the roots were reduced markedly. There was no consistent effect of excessive rainfall, as compared with medium or normal rainfall, upon starch and dry-matter contents of the roots. The starch content of the roots tended markedly to vary inversely with the degrees of latitude of the location where grown, but this tendency does not appear to be correlated with the rainfall, temperature, or length of growing season to which the crops were exposed for the last 4 mo. of the season. There was no clear association between starch content and soil fertility as indicated by yields.

Marked and consistent differences among varieties were evident in starch content as in yield. The relative starch content among varieties varied somewhat from year to year and from place to place, yet varietal differences were highly significant with reference to interactions of variety with season and with locality. Several seedlings, as B196 and B219, and introductions, as Wenholz 1, Wenholz 2, Director, and Wannop, were significantly superior to varieties commonly grown in the United States in starch content, yield of roots, and in quantity of starch produced per acre. Many varieties performed better in some places than in others, although a few were outstandingly good in all tests. Low-yielding or mediocre strains observed in any of the locations involved evidently can be discarded more promptly than formerly. It appears feasible to obtain superior new varieties of such wide adaptability that a multiplicity of kinds will not be needed to meet regional or local requirement.

Chlorophyll and carotene content of eighteen tobacco varieties, R. B. GRIFFITH, W. D. VALLEAU, and R. N. JEFFREY. (Ky. Expt. Sta.). (*Plant Physiol., 19 (1944), No. 4, pp. 689–693*).—The average chlorophyll concentration of 7 dark tobacco varieties calculated on a leaf-area basis was 107 percent larger than that of

11 burley varieties and their carotene content 87 percent greater, and on oven-dry weight basis these were 53 and 38 percent greater, respectively. All dark varieties averaged higher than the burleys in both pigments on leaf-area basis, but there was some overlapping in carotene on a weight basis. About half of the differences in pigment concentration of the two types may be attributed to difference in leaf thickness. The percentage of chlorophyll *a* differed little between varieties but significantly so between the earlier and later sampling dates. No correlation was found between chlorophyll or carotene contents and mosaic resistance factors. The average ratio, by weight, of total chlorophyll to carotene of all varieties studied was 19.75, very close to the ratio expected if nine molecules of chlorophyll *a* and three molecules of chlorophyll *b* were associated in the same protein group with one molecule of carotene.

Wheat varieties resistant to the hessian fly and their reactions to stem and leaf rusts, W. B. Cartwright, and R. G. Shands (*U. S. Dept. Agr., Tech. Bul. 877 (1944), pp. 6*).—A series of infestation tests were made, 1939–43, in the greenhouse and field at La Fayette, Ind., of about 3,000 domestic and foreign varieties and strains of wheat, to find those with resistance enough to hessian fly to be of value for commercial use or as parent material in breeding of fly-resistant varieties. About 6 percent of the wheats tested were found resistant. All found resistant appeared to be spring wheats except P. I. Nos. 119334 to 119358, inclusive, which have a winter growth habit. Most wheats were less infested in the field than in the greenhouse. Durums on the whole were more resistant than other varieties to hessian fly. Resistant spring wheats were especially common among introductions from Portugal, Argentina, and Uruguay. Several winter wheats moderately resistant were obtained from Turkey.

Most varieties listed were also tested for resistance to stem rust and leaf rust at Madison, Wis., in 1941 and 1942. A number showed a high degree of resistance to these rusts as well as to fly. Most common wheats tested were more or less susceptible to both stem rust and leaf rust. Five varieties from Portugal, Uruguay, and Argentina showed only traces of leaf rust, and 15 others showed only from 5 to 20 percent. Marquillo and Portugal 90 appeared to be most resistant to stem rust. Varieties of club wheat tested were more or less susceptible to both rusts and of poulard to stem rust. All durums were highly resistant to leaf rust. Certain durums appeared to offer good resistance to the hessian fly and to both leaf rust and stem rust, and may be especially useful in breeding programs.

Newthatch wheat, E. R. Ausemus, E. C. Stakman, E. W. Hanson, W. F. Geddes, and P. P. Merritt (*Minnesota Sta. Tech. Bul. 166 (1944), pp. 20, illus. 2*).—Newthatch, a hard red spring wheat, produced by crossing Hope with Thatcher and backcrossing to Thatcher twice and distributed to approved seed growers in 1944, resembles Thatcher (E. S. R., 75, p. 480) and has about the same date of heading and maturity, height, seed characters, and ability to withstand lodging. Newthatch has been resistant to both leaf and stem rusts. In the seedling stage, it proved resistant to 13 of 18 races of stem rust under test. It was outstanding in yield trials, 1941–43, being highest at University Farm and Crookston, second at Waseca, and third at Morris. In weight per bushel, Newthatch has exceeded Thatcher but was lower than Pilot, Rival, Regent, and Renown.

Newthatch has surpassed all other varieties in protein content and loaf volume, and has equaled them in yield of flour, in crumb color, grain, and crumb texture. It has a lower carotinoid pigment than Thatcher but a higher pigment content than the other varieties in the trials at the four stations. Color of the crumb of the bread has been satisfactory.

Newthatch wheat—What it is and what it took to make it, E. R. Ausemus and E. C. Stakman (*Minn. Farm and Home Sci.* [*Minnesota Sta.*], *2 (1944), No. 1,* *p. 13)*.—An account of the origin and characteristics of Newthatch, the new hard red spring wheat noted above.

Seed inspection in Kentucky, 1943–44, W. A. PRICE, M. L. DIDLAKE, E. C. VAUGHN, E. DEEN, H. TILSON, A. MCDANIEL, K. FRIED, M. MORTON, M. L. LITTELL, and L. BAUGH *(Kentucky Sta. Regulat. Ser. Bul. 40 (1944), pp. 32)*.—Germination and purity percentages and, when present, excessive quantities of noxious weed seed, are reported for 457 official samples of farm crop seed obtained from dealers during the year ended June 30, 1944.

Summary of results of seed and legume inoculant inspection for 1943, J. G. FISKE *(New Jersey Stas. Insp. Ser. 14 (1944), p. 25)*.—Dealers in New Jersey from whom 3,282 official samples of farm crop and vegetable seed and seeds mixtures were collected in 1943 are listed with compliances and violations, and vendors, crops, inoculations, and numbers of organisms are shown for 30 official samples of legumes inoculants collected in 1943.

Report on inspection of agricultural seed for 1944, L. S. WALKER and A. S. LUTMAN *(Vermont Sta. Bul. 518 (1944), p. 12)*.—Purity and germination guaranties and variations found are tabulated and discussed from tests of 325 samples of field crops seeds and forage mixtures secured from dealers in Vermont in 1944.

Weeds that may become noxious, A. H. HOLMGREN *(Farm and Home Sci. [Utah Sta.], 5 (1944), No. 4, pp. 8–9, 15, illus. 11)*.—Weeds now restricted to certain areas of Utah but potentially serious pests, described and illustrated, are nutgrass (*Cyperus esculentus*), halogeton (*Halogeton glomeratus*), field buttercup (*Ranunculus arvensis*), and madder (*Rubia tinctorum*).

Is there a better way to eradicate noxious weeds, R. J. EVANS *(Farm and Home Sci. [Utah Sta.], 5 (1944), No. 4, pp. 7, 13, illus. 2)*.—A whitetop control program, based on results of cropping treatment of infested areas, includes clean cultivation of the land the first year, check-planted corn cultivated every 2 weeks or as often as needed to keep down weeds the second year, and sugar beets the third year. Chemicals should be used in the fence lines and along ditch banks. Where immediate eradication is not practicable weeds may be kept under control and their vigor diminished greatly by a rotation such as barley, rotation pasture (or alfalfa 3 yr.), check planted and cross cultivated corn 1 yr., and sugar beets 1 yr. Weights of whitetop roots are shown for each treatment.

The chemical control of Klamath weed.—I, Application of ecological methods in determining the herbicidal and fertilizing properties of ammonium sulfamate and commercial borax, B. E. ALLGAIER. (Wash. State Col.). *(Ecology, 25 (1944), No. 4, pp. 424–432, illus. 4)*.—Range near Lapwai, Idaho, infested with Klamath weed or St. Johnswort (*Hypericum perforatum*) (E. S. R., 78, p. 780; 85, p. 618) was treated April 11, 1943 with ammonium sulfamate and borax, separately and in combination as dust and as sprays, and crested wheatgrass was broadcast on subplats under each treatment from April 25 to July 4. Weed counts and the staggered grass-planting dates revealed that ammonium sulfamate was a better herbicide than borax at the same rate, and also was more active as a subsequent fertilizing agent. Absolute weed control was obtained after 2 weeks in the ammonium sulfamate spray plat and after 4 weeks in the dust plat, while 8 weeks were required for a maximum control of 83 percent in the borax spray plat and 14 weeks for an 84 percent maximum in the dust plat. Grass sown on the ammonium sulfamate spray plat showed an acceleration in growth about 10 times that in the borax spray plat. The increase in growth under dust treatment was about 25 percent over the borax dust plat.

HORTICULTURE

Some plant and insect problems of Kentucky nurserymen during the year ended June 30, 1944, W. A. Price and H. G. Tilson *(Kentucky Sta. Regulat. Ser. Bul. 41 (1944), pp. 20).*—Information is presented on various insect and fungus pests, requirements of the Kentucky nursery inspection law, personnel in charge of inspection in the various States, lists of Kentucky nurserymen whose plantings were inspected in 1943–44, and lists of nursery dealers and nonresident nurserymen.

Analyses of materials sold as insecticides and fungicides during 1943, C. S. Cathcart and R. L. Willis *(New Jersey Stas. Insp. Ser. 12 (1943), pp. 19).*——Herein are presented in the usual manner (E. S. R., 89, p. 214) the results of analyses of materials collected during the 1943 inspection.

Sphagnum moss for seed germination, V. T. Stoutemyer, A. W. Close, and C. Hope *(U. S. Dept. Agr. Leaflet 243 (1944), pp. 6, illus. 7).*—Shredded sphagnum moss was found an ideal medium for seed germination in tests conducted with many different species of plants. The use of sphagnum removed the necessity of applying chemical protectants to the seeds or seeding medium and prevented harm from overwatering. If mineral nutrient solutions are used many plants make excellent growth beyond the seedling stage. Details of preparing the sphagnum, use of nutrient solutions, and handling the young seedlings are presented.

The pollination and spatial isolation of vegetable seed crops, G. Haskell *(North West. Nat., 19 (1944), No. 1–2, pp. 34–44).*—Data are presented for various members of the Cruciferae, Leguminosae, Umbelliferae, Cucurbitaceae, Compositae, Solanaceae, Chenopodiaceae, Liliaceae, and Gramineae.

Storage and drying of vegetables (*Alabama Sta. Rpt. 1941, pp. 21–22*).—Experimental results indicated that galvanized iron roofs exposed to full sunlight are useful in drying vegetables. On summer days the temperature on such roofs reaches about 110° F. at 8 a. m. and rises to 125°–137°, where it remains for several hours. Even on relatively cool autumn and winter days, the temperatures may rise above 100°. Among crops dried on roofs were shelled cowpeas, lima beans, soybeans, rape, mustard and turnip greens, and sliced roots of carrot, rutabagas and turnips. Other crops handled more or less successfully included sweetpotatoes, potatoes, and pimiento peppers.

Effects of 2,4-dichlorophenoxyacetic acid on the ripening of detached fruit, J. W. Mitchell and P. C. Marth. (U. S. D. A.). *(Bot. Gaz., 106 (1944), No. 2, pp. 199–207, illus. 1).*—Observations on the effects of 2,4-dichlorophenoxyacetic acid on the subsequent ripening of detached fruits and vegetables indicated that the chemical when applied either in aqueous solution with some wax or by the aerosol method hastens the ripening of bananas, apples, and pears, but on the basis of color changes had little effect on the ripening of the tomato, pepper, and persimmon, fruits which are generally without an appreciable starch reserve. Starch hydrolysis proceeded at a more rapid rate during the ripening of treated bananas, as shown by both iodine and taste tests.

Suggestions on irrigating commercial truck crops, L. D. Doneen and J. H. MacGillivray *(California Sta., [1943], pp. 5, illus. 7).*—This leaflet discusses the function and movement of soil moisture, the water-holding characteristics of soils, effect of soil structure on water penetration and depth of rooting, indications of a lack of soil moisture, determination of need of irrigation, factors affecting the frequency of irrigation, irrigation of the seedbed, depth of rooting of various truck crops, their irrigation needs, etc.

The characteristics of crosses between botanical varieties of cabbage, Brassica oleraceae, A. F. Yeager *(New Hampshire Sta. Sci. Contrib. 90 [1943], pp. 199–200).*—This study was noted earlier (E. S. R., 90, p. 623).

Effect of daylength on growth and reproduction of the cucumber, L. L. DANIELSON *(Plant Physiol., 19 (1944), No. 4, pp. 638–648, illus. 3)*.—Quantitative and qualitative determinations were made at intervals throughout the growing period on vines of gherkins growing in contrasting daily photoperiods of 8, 12, and 16 hr. and from which all lateral branches and flowers were removed as formed. Under the conditions stem elongation was retarded by 16-hr. photoperiods. Maximal stem elongation occurred in 8-hr. day length plants. Contrasted vegetative responses to day length became especially evident with onset of flowering, suggesting that the photoperiodic reaction of the stem is in some manner physiologically related to, if not dependent upon, the onset of flowering. Maximum staminate flower production on the basis of total number produced occurred in the 8-hr. day. Quantitative measurements of stem, leaf, and root growth as well as chemical composition showed that vegetative responses peculiar to each day length occurred.

Derris grows in America, R. H. MOORE *(U. S. Dept. Agr., Agr. in Americas 5 (1945), No. 1, pp. 10–12, 16, 18, illus. 4)*.—Among items discussed are the beginnings of derris culture in Puerto Rico, propagation, preparation of plants for shipment and planting, varieties, climatic requirements, culture, potential possibilities in the Western Hemisphere, etc.

Safflower, a possible economical oil-seed crop for Utah, D. W. PITTMAN *(Farm and Home Sci. [Utah Sta.], 5 (1944), No. 4, p. 15)*.—Safflower, long grown as an oil-seed crop in the arid desert regions of the Near East was tested and found capable of producing satisfactory crops of seed with a small amount of irrigation water. The potential uses of the crop are discussed.

Station conducts tests on growing sage for seasoning under irrigated methods, A. M. BINKLEY *(Colo. Farm Bul. [Colorado Sta.], 6 (1944), No. 5, pp. 3–5, illus. 2)*.—Herein are presented the results of tests in producing sage, a product which in peacetime is largely imported. Computed yields per acre were 131 lb. the year of setting and 1,373.0 and 2,442.9 lb. the succeeding 2 yr. Under present high prices some profit could be realized, but high cost of harvesting might well prohibit production under ordinary circumstances.

Pruning and training tomatoes in the South, M. T. DEONIER, G. P. HOFFMAN, C. E. STEINBAUER, and L. R. FARISH. (Coop. Miss. Expt. Sta.). *(U. S. Dept. Agr. Cir. 712 (1944), pp. 16, illus. 2)*.—The results of a series of experiments, carried on at several locations in Mississippi, indicated that under the conditions prevailing pruning and training were good practices when tomatoes are grown for shipment, especially for early markets, and when labor and materials are available. Of various methods tested, pruning and training to two stems gave the best results. Topping did not prove to be a worth-while practice. The fruit obtained from an acre of pruned and staked plants, spaced 2 by 4 ft., had a greater net value than that from an acre of unpruned plants set 4 by 4 ft. The average size of all the marketable tomatoes was larger on the pruned and staked plants, while the size of the early ripe fruits was apparently unaffected. The pruned and staked plants yielded slightly lower percentages of No. 3 and cull fruits, and slightly larger percentages of cat-faced fruits and fruits affected with blossom-end rot.

Influence of phosphorus supply and the form of available nitrogen on the nitrogen metabolism of the tomato plant, W. S. BREON and W. S GILLAM. (Ind. Expt. Sta.). *(Plant Physiol., 19 (1944), No. 4, pp. 649–659)*.—Tomatoes growing in a medium supplying nitrate as a source of nitrogen and moderately but definitely showing symptoms of phosphorus deficiency revealed an accumulation of nitrates in all parts of the plant. This condition is shown to be due to accumulation following more rapid absorption rather than to nonutilization. Plants receiving N in the form of urea, grew rapidly and vigorously as long as the pH of the culture solution was maintained at 6.8–7.0. At pH 4.8–5.0 growth was greatly

ENTOMOLOGY.

Insects of the clover field, G. C. DAVIS (*Michigan Sta. Bul. 116, pp. 41–64, figs. 11, pl. 1*).

Synopsis.—This bulletin consists of 2 parts, the first dealing with insects destructive to clover, comprising 4 species attacking respectively the root, leaf, seed, and hay; and the second giving brief notes on 8 species that are designated as common but not destructive.

Insects destructive to clover (pp. 41–58).—Illustrated notes on the appearance, life history, ravages, and treatment of the clover-root borer (*Hylastes obscurus*), clover-leaf weevil (*Phytonomus punctatus*), clover-seed midge (*Cecidomyia leguminicola*), and clover-hay worm (*Pyralis costalis*). The clover-root borer made its appearance in the State in 1889 and rapidly spread over the middle and southern portions, extending west to Lake Michigan. The greater destruction has been in the southern part, its progress being slower toward the north owing to the sandy forest regions. A map is given showing its distribution in the State. Investigations show that the imagoes first appear early in May, and the latter part of the month begin depositing their eggs in the galleries bored in the clover roots where they have hibernated. The larvæ begin to pupate about July, issuing as adults in the fall and passing the winter in that state. Red clover and mammoth clover suffer most severely, although alsike is also attacked. White clover seems to be exempt. The plants are rarely attacked until they are a year old. Experiments with nitrate of soda, muriate of potash, and kainit, applying them at the rate of half a ton and a ton per acre, were made, but the beetles were apparently unaffected, while the plants were seriously injured and some of them killed. Plowing under in the spring of the second year, or plowing in the summer and thus exposing the roots and young larvæ to the sun, are suggested as the only remedies at present known.

The clover-leaf weevil is found in all parts of the State except the northern, and has done considerable damage. This season the pest was destroyed in great numbers by a fungus disease (*Empusa sphærosperma*). This rapidly killed the larvæ, which before dying crawled up blades of grass and coiled themselves around the tips. In one instance, cattle feeding upon such grass were rendered sick, though no serious result ensued. A report on this fungus attack, by C. F. Wheeler, is included.

The clover-seed midge is considered the most dangerous enemy of the clover crop in the State, the flies depositing their eggs over the clover head before the florets open, and the maggots crawling into the flower tubes and making their way into the forming seed. The eggs for the first brood are laid in May, and for the second in July. Mammoth and common red clover are most attacked, alsike not being molested. Pasturing clover fields through the spring and early summer is recommended, or early cutting of the crop before the larvæ of the first brood have matured and dropped from the seeds to the ground to pupate.

The clover-hay worm is found only in dry clover hay, the eggs being deposited in June and the larvæ feeding throughout the rest of the year, and changing into moths the following spring. Clean mowing is advised and never storing clover hay 2 seasons in the same mow. Where hay is attacked, bisulphid of carbon may be applied, 3 or 4 lbs. to each ton, and the hay covered with heavy blankets for a few days.

Insects that are common but not destructive (pp. 58–64).—This part of the bulletin comprises illustrated descriptive, life history, and remedial notes on the following insects: Clover-root mealy bug (*Dactylopius trifolii*), clover-stem borer (*Languria mozardi*), common yellow butterfly (*Colias philodice*), clover drasteria (*Drasteria erechtea*), clover-head caterpillar (*Grapholitha interstinctana*), clover-head thrip (*Phlœothrips niger*), and the white-winged fly (*Bibio albipennis*).

The scale insect of mulberry trees, C. SASAKI (*College of Agr., Tokyo, Japan, Bul., vol. 2, No. 3, pp. 107–124, pls. 2*).—Illustrated descriptive and life-history notes on a scale insect of importance to the silk industry in the East, and which is technically described as a new species (*Diaspis patelliformis*).

The male is orange red, with yellow appendages, and 0.8 mm. long by 0.25 mm. broad. The wing expanse is 2 mm. The female is oval, light yellow, and possesses 9 segments, the third to the ninth being margined with a number of minute fine spines, simple or branched. There are two broods, the adults appearing in June and October, and the males dying soon afterwards, while the females of the second brood live through the winter on the mulberry bark. The larvæ in the first two stages of growth are oval, flat, and yellow, with 2 black eyes. At first they are very active, but after the second molt they become fixed to the bark and change into pupæ.

The species is found over nearly all of Japan, where it attacks chiefly the mulberry, but also some other trees, the branches frequently being completely covered with scales and the trees greatly injured. A crude method of treatment is to scrape off the scales from the bark, but spraying with limewater, kerosene emulsion, or a mixture of water, fish oil, and bicarbonate of soda, is recommended. A Chalcid and a Coccinellid prey upon the scale.

Some insects injurious to shade trees, J. B. SMITH (*New Jersey Stas. Bul. 103, pp. 15, figs. 4*).—Descriptive life history and remedial notes on the elm-leaf beetle (*Galeruca xanthomelæna*), wood leopard moth or imported elm borer (*Zeuzera pyrina*), and the white-marked tussock moth (*Orgyia leucostigma*). Spraying with London purple, Paris green or arsenate of lead is recommended for the elm-leaf beetle, an application to be made when the beetles are first noticed, a second when the larvæ begin to hatch, and a third 10 days later. The only remedy available against the wood leopard moth appears to be cutting down and burning all infested trees and branches, or pouring a few drops of bisulphid in the burrows and closing the opening with putty. It is recommended that the egg masses of the tussock moth be removed from the trees during the winter and burned, and that the caterpillars be sprayed in June with some one of the arsenites.

General remarks on protecting shade trees from insect attacks are given, and a list of 21 shade trees, in the order of least susceptibility to insect injuries.

Insect Life (*U. S. Dept. Agr., Division of Entomology, Insect Life, vol. VII, No. 2, pp. 55–215, fig. 1*).—This number is devoted to the proceedings and papers of the sixth annual meeting of the Association of Economic Entomologists, which met at Brooklyn, New York, August 14 and 15, 1894.

Brief account of the rise and present condition of economic entomology, L. O. Howard (pp. 55–107).—This paper consists of a historical sketch of economic entomology from the Middle Ages to the present time, giving in detail the growth and extent of this science in the United States, Canada, Great Britain, Germany, Austria-Hungary, Italy, France, Spain, the Netherlands, Norway, Sweden, Russia, Finland, South America, India, South Africa, Australia, the West Indies, New Zealand, and Hawaii. The scope and value of the work in the different countries is treated at length and the various investigators mentioned. The entomological work of the experiment stations is reviewed and a bibliographical list of their publications given.

Bisulphid of carbon as an insecticide, J. B. Smith (pp. 108–110).—An account of experiments with this chemical against melon lice, a dram of the liquid being placed in a saucer or small tumbler by each hill and the whole covered with a large wooden bowl. This was left undisturbed for an hour, when upon examination all the aphides were found to be killed. In the ensuing discussion the method was spoken of by several members favorably and modifications suggested.

Report of committee on coöperation among station entomologists, J. B. Smith (pp. 112–114).—Recommendations of lines of work in which entomologists may assist one another, notably in the study of life histories and geographical distribution, and the testing of insecticides.

Spraying without a pump, J. M. Aldrich (pp. 114, 115).—A preliminary note on an apparatus for mixing kerosene with water at the instant of passing through the nozzle, thereby doing away with the necessity of making kerosene emulsion.

Notes on insecticides, C. L. Marlatt (pp. 115–126).—General remarks on the scientific use of insecticides and notes on experiments with applications of standard insecticides, new insecticides, and modifications of old ones. The new peach scale (*Diaspis linatus*) and the euonymus scale (*Chionaspis euonymi*) were the species against which most of the experiments were directed, and kerosene emulsion proved most beneficial. Arsenate of lead was satisfactorily tested against the elm-leaf beetle, and Bordeaux mixture was combined with kerosene emulsion with good results.

Some observations on new and old insecticides and their combination with fungicides, B. T. Galloway (pp. 126–131).—General accounts of experiments in this line, notably with Bordeaux mixture combined with various insecticides, such as kerosene emulsion, Paris green, and resin wash, with formulas for the preparation of the various mixtures.

Spraying with arsenites vs. bees, F. M. Webster (pp. 132–134).—In order to determine definitely the injurious effect on bees, produced by spraying fruit trees when in bloom, two blossoming apple trees were sprayed with Paris green and bees caught visiting the flowers were analyzed. Traces of arsenic were found in the abdomens and honey sacs, though the exteriors of the bodies gave none of the poison. Bees and larvæ showing traces of arsenic were also found dead in and about adjacent hives, and in consequence it is urged that fruit trees be not sprayed before the falling of the bloom.

Economic entomological work in the parks of New York City, E. B. Southwick (pp. 135–138).—General remarks on the treatment of injurious insects in the New York City parks, with notes on several species, especially *Orgyia leucostigma*, *Zeuzera pyrina*, sap fly, and the elm-leaf beetle. Streams of water were sprayed upon plant lice by means of hose, with good results.

The wood-leopard moth in the parks of New York City, E. B. Southwick (pp. 138–140).—Notes on the life history of *Zeuzera pyrina* and the injuries caused to trees by it.

Work in economic entomology at the University of Kansas for the season of 1894, F. H. Snow (pp. 140–144).—Notes on satisfactory treatment of the chinch bug with *Sporotrichum globuliferum*, and upon *Agrotis introferens*, which cutworm was destructive to alfalfa and wheat.

Notes on some discoveries and observations of the year in West Virginia, A. D. Hopkins (pp. 145–151).—Life histories and notes on various injurious insects, especially the Columbian bark beetle (*Corthylus columbianus*), the potato-scab gnat (*Epidapus scabies*), and the chestnut timber worm (*Lymexylon sericeum*).

The eastern occurrence of the San José scale, L. O. Howard (pp. 153–163).—A review of the recent attacks of the San José scale in the eastern United States, with mention of the infested localities and a detailed account of the remedial treatment. The pest was spread from New Jersey nurseries that had distributed infested trees procured from California. A scymnid beetle (*Pentilia misella*) has been found to feed upon the scale.

The San José scale in New Jersey, J. B. Smith (pp. 163–167).—Notes on the occurrence of the pest in the State, with the treatment applied. Pears were chiefly attacked.

Mealy bugs and their allies, G. C. Davis (pp. 168–175).—Descriptive and life-history notes on *Dactylopius destructor*, *D. longifilis*, *D. trifolii*, and *Aleyrodes vaporarium*, with accounts of experiments.

The pear-tree psylla in Maryland, C. L Marlatt (pp. 175–185).—Notes on a sudden and overwhelming invasion of *Psylla pyricola* in two large pear orchards of southern Maryland, where the pest was introduced from a New York nursery. Twenty thousand trees were affected, and experiments were made with different emulsions against the pest. Kerosene emulsion applied when the eggs are hatching in the spring and winter spraying with a strong solution of the same are recommended. The lace-wing fly (*Chrysopa oculata*) and a ladybird, *Adalia bipunctata*, were effective destroyers of the psylla.

Notes of the year in New Jersey, J. B. Smith (pp. 185–197).—More or less detailed notes on injurious insects, especially the San José scale, pear psylla, pear midge, pear borer (*Agrilus acutipennis*), seventeen-year locust, and melon louse.

Special economic insects of the season, G. C. Davis (pp. 198–201).—Notes on *Diplotaxis harperi* attacking strawberries, a raspberry maggot (*Adimonia cavicollis*) on cherry foliage, *Notoxus anchora* eating cherries, and *Mononychus vulpeculus* destroying iris flowers.

Additional notes on the strawberry weevil, its habits and remedies, F. H. Chittenden (p. 201).—This paper was published in Insect Life, vol. VII, No. 1, pp. 14–23 (E. S. R., 6, p. 562).

Notes on the insects of north Idaho, J. M. Aldrich (pp. 201, 202).—General notes on several common fruit pests imported from the East.

Insects of the year, F. M. Webster (pp. 202–207).—Notes on various insect attacks, particularly those of the clover-leaf weevil, and a thrips, probably *Limothrips tritici*, which caused serious injury to onions.

Notes from New Mexico, T. D. A. Cockerell (pp. 207–211).—General remarks on insects in the Mesilla Valley and about Santa Fe.

Some experiences with mosquitoes, H. E. Weed (pp. 212, 213).—Notes on destroying mosquito larvæ by placing kerosene on the surface of the water where they bred.

A list of the American and foreign members of the association is appended.

Bordeaux mixture as a deterrent against flea beetles, L. R. JONES (*Agl. Sci., 8 (1894), No. 6–9, pp. 364–367, pls. 2*).—In consequence of the attacks of the cucumber flea beetle on potato plants in Vermont being scarcely at all checked by applications of Paris green, experiments were made with different strengths of Bordeaux mixture, ammoniacal copper carbonate, and modified eau celeste to ascertain their value as insecticides. The results were most satisfactory and far superior to those obtained by dusting the infested plants with a mixture of Paris green and land plaster. It is recommended that 2 applications of a strong solution of Bordeaux mixture be made, the first early in June, and another in July, which will in most cases be sufficient. Soap mixed with the solution was found to add slightly to its insecticidal value.

Farm practice and fertilizers as insecticides, J. B. SMITH (*Ontario Ent. Soc. Rpt. 1893, pp. 68-70*).—This paper treats of combating injurious insects by means of cultural methods, chief among which are suggested manuring with chemical fertilizers. Nitrate of soda and kainit are considered especially valuable, and the peach aphis, corn webworm, cabbage maggot, and wireworm are stated as insects against which these chemicals have been used effectively. Intelligent rotation of crops is also suggested.

Experiments with Botrytis tenella for destroying white grubs (*Deut. landw. Presse, 21 (1894), No. 88, pp. 828, 829*).—Four cages were made and the bottoms filled with earth, in which lettuce was planted, and after the plants were growing vigorously 25 white grubs were introduced into each cage. The grubs were buried at different depths in the earth, and 2 of the cages were kept very moist, while the other 2 were allowed to become quite dry. Two grubs were then infected with *Botrytis*, by being shaken up in a test tube with water and spores of the fungus, and placed one in a moist and the other in a dry cage. Two months afterwards the cages were examined, and though the experiment was interfered with by a severe mortality of the grubs, occurring in the check cages as well as in those infected, yet, since only 2 grubs remained alive in the infected damp cage as against several in the others, the destructive power of *Botrytis* under moist conditions is believed in. The fungus did not seem to act in the dry cage infected.

The spermatogenesis of the silkworm, K. TOYAMA (*College of Agr., Tokyo, Japan, Bul., vol. 2, No. 3, pp. 125-157, pls. 2*).—Technical embryological, anatomical, and physiological notes of investigations of this subject, with extensive figures.

The dragon fly, T. J. MACLAUGHLIN (*Ontario Ent. Soc. Rpt. 1893, pp. 55-60, figs. 6*).—Semipopular descriptive and systematic notes on some of the common dragon flies, their habits and effectiveness in destroying mosquito larvæ being particularly dwelt upon.

Mosquitoes, J. A. MOFFAT (*Ontario Ent. Soc. Rpt. 1893, pp. 43-48*).—General and popular notes on the geographical distribution and life history of *Culex pipiens*, with a discussion of the anatomy of the mouth parts and the physiological action of the bite. Burning pyrethrum powder in the house is recommended, as also growing castor beans and treating stagnant pools with kerosene.

Effects produced by ticks upon their hosts (*Agl. Jour. Leeward Islands, 1894, Oct., pp. 36-44*).

The cheese or meat skipper, M. E. MURTFELDT (*Ontario Ent. Soc. Rpt. 1893, pp. 98-101*).—Notes on the history, ravages, and life history of *Piophila casei*, the use of screens being advised as a preventive.

A new scale insect found on plum, T. D. A. COCKERELL (*Canadian Ent., 27 (1895), No. 1, pp. 16-19*).—*Aspidiotus howardi* is described as a new species from Colorado.

The bud moth, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1893, pp. 27-52, figs. 8*).—A reprint of Bulletin 50 of the station (E. S. R., 4, p. 930).

The four-lined leaf bug, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1893, pp. 217–248, figs. 13*).—A reprint of Bulletin 58 of the station (E. S. R., 5, p. 406).

Grasshoppers, J. FLETCHER (*Ontario Fruit Growers' Assn. Rpt. 1893, pp. 29–32*).—General and popular notes on the invasions of these insects, life history and treatment being given. A mixture of bran, arsenic, and sugar is recommended.

Destructive Scolytids and their imported enemy, A. D. HOPKINS (*Ontario Ent. Soc. Rpt. 1893, pp. 71–75*).—General remarks on the habits of various Scolytid bark beetles, especially *Dendroctonus frontalis* and *D. terebrans*, with notes on the introduction of *Clerus formicarius* from Germany to combat them. About 3,000 specimens of the latter beetle have been imported and placed in different sections of the pine forests in West Virginia, with already beneficial results.

Keys to the genera of Pediculidæ and Mallophagidæ, H. OSBORN (*Amer. Monthly Micr. Jour., 15 (1894), n. ser., No. 11, pp. 344–346*).—Technical analytical synopses of these lice.

Preliminary studies in the Siphonoptera, C. F. BAKER (*Canadian Ent., 27 (1895), No. 1, pp. 19–22*).—The first part of a technical paper.

Insect foes of American cereal grains, with measures for their prevention or destruction, F. M. WEBSTER (*Ontario Ent. Soc. Rpt. 1893, pp. 88–93*).—Notes on some of the more important insects attacking corn, wheat, and oats, the Hessian fly, chinch bug, Isosomas, apple-leaf louse, wireworms, white grubs, and cutworms being especially treated of.

Parasitic and predaceous insects in applied entomology, C. V. RILEY (*Ontario Ent. Soc. Rpt. 1893, pp. 76–84*).—General discussion of the value to man of the parasitic and predaceous insect enemies of such species as injure vegetation, with special remarks on some of the more important injurious insects and their enemies. Insects preying upon scale insects are especially mentioned and the Capri fig insect (*Blastophaga psenes*) is stated as almost invaluable in the fertilization of fig blossoms.

Injurious insects, W. H. HARRINGTON (*Ontario Ent. Soc. Rpt. 1893, pp. 17–31*).—Descriptive, life history, and remedial notes on the larch sawfly, rose sawflies, pear-tree slug, Cornel sawfly, fall cankerworm, and a few other insects of less injuriousness. Parasitism in insects is briefly treated of, and a careful study of entomological publications urged.

Injurious insects of the year, J. FLETCHER (*Ontario Ent. Soc. Rpt. 1893, pp. 8–13, figs. 8*).—This paper treats of some of the most important insect attacks of the season, particularly a maple gall moth, a squash carrion beetle, cutworms, turnip flea, horn fly, and locusts.

Insects injurious to plants, L. WOOLVERTON (*Ontario Fruit Growers' Assn. Rpt. 1893, pp. 101–106*).—A more or less popular paper on the life history and treatment of the codling moth, curculio, oyster-shell bark louse, pear-tree psylla, raspberry gallfly, and the parasites of the latter.

Nurseries as factors in the distribution of insect pests, J. B. SMITH (*Agl. Sci., 8 (1894), No. 6–9, pp. 361–363*).—A short discussion of the subject, citing the San José scale as an example of an injurious insect spread by nursery stock, and urging that the utmost care be exercised both by nurserymen and by orchardists to avoid the introduction of insects and plant diseases that have proved injurious elsewhere.

Report of entomologist, P. H. ROLFS (*Florida Sta. Bul. 24, p. 19*).—Brief mention of the entomological work during the year, specimen cases and rearing cages being added to the station outfit.

Arsenical spraying of fruit trees while in blossom, J. A. LINTNER (*Ontario Ent. Soc. Rpt. 1893, pp. 102–104*).—A discussion of the experiments in regard to the poisoning of bees from the spraying of fruit trees with arsenites, and urging more careful and extended investigations. The effect of the poisoning on the blossoms, fruit development, and leaves is remarked upon, and some of the insects checked by spraying are mentioned.

Methods of attacking parasites of domestic animals, H. OSBORN (*Ontario Ent. Soc. Rpt. 1893, pp. 96, 97*).—General notes on the subject, especially mentioning the treatment of bots by washes and dipping, and of lice by fumigation with sulphur or tobacco.

Fumigation with bisulphid of carbon for the complete and rapid destruction of insects which attack herbarium specimens, furs, woolens, etc., H. DU BUYSSON (*Ontario Ent. Soc. Rpt. 1893, pp. 94, 95*).—Detailed directions for the use of this insecticide for the purposes mentioned.

Protection of asparagus from insect enemies, E. OSCHENDORFF (*Deut. landw. Presse, 21 (1894), No. 78, p. 793*).—Notes on preventive treatment of several insects, especially the asparagus beetle.

Remedies against the grass cutworm (*Ztschr. landw. Ver. Hessen, 1894, No. 23, pp. 185, 186*).—General notes on ravages by the caterpillars of *Charæas graminis*. Kerosene emulsion seems to be preferred as an insecticide.

The rose chafer or rose bug, how to deal with it, F. M. WEBSTER (*Ohio Hort. Soc. Rpt. 1893-'94, pp. 87-91*).—Life-history notes on *Macrodactylus subspinosus*, and the results of experiments in combating it. Plowing the sandy soil in which the insect breeds 3 in. deep in May and early June is recommended, and hand picking the adults.

A remedy for insects injuring sugar cane, F. A. F. C. WENT (*Sugar Cane, 26 (1894), No. 303, pp. 551, 552*).—Notes on experiments.

Circumstances favoring the extension of fungus diseases among insects, P. VUILLEMIN (*Rev. Mycol., 17 (1895), No. 1, pp. 21, 23*).

The economic value of parasites and predaceous insects, J. B. SMITH (*Ontario Ent. Soc. Rpt. 1893, pp. 84-87*).—General discussion of the subject, with particular reference to the insect enemies of scale insects, potato beetles, cranberry insects, codling moth, and melon louse.

Investigations of bacteria infesting caterpillars, K. ECKSTEIN (*Ztschr. Forst.- und Jagdw., 26 (1894), No. 1, p. 3; No. 4, p. 228; No. 5, p. 285*).—Notes on some experiments with insect bacterial diseases, with varying success.

FOODS—ANIMAL PRODUCTION.

Mannane as an article of human food, C. TSUJI (*College Agr., Tokyo, Japan, Bul., vol. 2, No. 2, pp. 103-105*).—There are sold in Japan as food gelatinous colorless tablets made from the tuberous rootstocks of *Amorphophallus rivieri durien*, a plant belonging to the *Aroideæ* and largely cultivated in Japan. These tablets appear to consist of starch paste, but do not give any reaction with iodin, and the author's investigations indicate that they are composed of mannane, a polyanhydrid of mannose. The dried ground rootstock yielded 55.86 per cent of mannose. All attempts to convert the mannose of this powder into a sugar by diastase were unsuccessful.

Rations fed to milch cows in Connecticut, C. D. WOODS and C. S. PHELPS (*Connecticut Storrs Sta. Bul. 13, pp. 16*).—In the Annual Report of the station for 1893 (E. S. R., 6, p. 458) the details were given of the study of the rations fed to 16 herds of cows in Connecticut. In the winter of 1893-'94 this study was continued on 6 herds. A representative of the station visited these farms and remained during the test, which in 4 cases lasted 12 days, weighing and testing the milk, weighing the foods and sampling them for analysis, and collecting statistics as to the breed, age, period of lactation, etc., of the cows. As soon as the analyses of the feeding stuffs could be made the rations were calculated and in 3 cases other rations were suggested. The feed was gradually changed to the suggested ration, and after 4 weeks from the close of the first test another 12 days' test was made. The summary of the results of these 2 tests at the 3 farms is given in the following tables, test No. 1 indicating the original ration and No. 2 the suggested ration in each case:

Summary of daily rations fed and daily milk and butter yield from three herds with a wide and a narrower ration.

Herd.	Average weight of cows.	No. of test.	Daily ration per head.					Average daily—		Total cost of food to produce—	
			Digestible protein.	Fuel value of digestible nutrients.	Nutritive ratio.	Total cost.	Net cost.	Milk flow.	Yield of butter.[1]	100 lbs. milk.	1 lb. butter.

[1] Butter assumed to contain 85 per cent butter fat.

"At the time of the second test in each case the cows were 6 weeks further along in the period of lactation, and would in consequence have naturally reduced their milk flow and butter yield. . . .

"In the case of herd A, instead of a falling off in milk flow there was an average daily increase of seven tenths of a pound in the test while they were fed the narrow ration over what it had been with the wide ration 6 weeks earlier. There was practically no change in milk flow in the case of the two other herds. With all three herds there was a slight increase in butter yield with the narrow ration in the second test. The total size of the ration as measured by the fuel value averaged less in the second test than in the first. The protein was increased and the carbohydrates and fats were decreased in the second test.

"In these cases both milk flow and butter yield were so much affected by a change from a wide to a narrow ration that instead of a shrinkage in production, as would naturally follow from advancement in period of lactation, the animals more than held their own. . . .

"The cost of milk and butter production from the food alone was much less on the narrower ration, even when the cows were 6 weeks further advanced in lactation than earlier on the wide ration. So far as these tests may be taken as an indication, narrow rations may be fed more profitably than wide."

The rations of the 16 herds studied previously are arranged according to nutritive ratio and amount of protein in the ration. A comparison of these data with the yields of milk and butter develops the following facts:

"The animals having the narrower rations produced on the average one tenth of a pound more of butter per day than those having the wider, and those having the larger amounts of protein gave, on the average, two tenths of a pound more of butter per day than those having the smaller quantities of protein. Too much importance should not be attached to these results, as they may have been partly accidental, and due to causes other than feed. It is, nevertheless, a noteworthy fact that in the cases in which the cows were in about the same period of lactation, the yields of butter decreased as the protein decreased, and as the nutritive ratio increased. This would seem to indicate that it would be safe in general to feed as much or even more protein than called for by Wolff's standard ration if we would obtain the largest yields of butter from our milch cows."

Feeding experiments with fat-extracted fish meal for cows, KÜHN-CORNIETEN (*Molk. Ztg., 81 (1894), No. 44, p. 675*).—A practical trial with 6 cows. Ground fish, freed from fat, was gradually introduced into the ration as a substitute for brewers' grains and sunflower-seed cake. From 1¼ to 2¼ lbs. (German) per head was fed, and several analyses of the milk were made at the Königsberg station. The yield and composition were fairly well maintained on the fish meal. In regard to the quality of the milk and butter, Professor Klein, of the Königsberg station, reported that they did not differ especially from that produced on oil cakes. After keeping for a half year the butter, although it was somewhat rancid and tasted old, had no fishy or unusual taste. The fish meal had no ill effects upon the cows.

Comparative value of mixed grain and wheat bran or shorts for milch cows, F. FRIIS (*Kgl. Vet. Landt. Lab. Landökon. Forsög., Copenhagen, Bul. 29, 1894, pp. 76*).

Synopsis.—Feeding experiments conducted during 1893 and 1894 by the State experiment station at Copenhagen, Denmark, at 7 different estates with 447 cows in all. Mixed oats and barley were compared with wheat bran and with wheat shorts. No appreciable difference was found as to the effect of the feeds given on either yield or composition of the milk produced. The tendency was toward a slight superiority of the bran over the grain, and of shorts over the bran.

The report describes the sixth and seventh series of feeding experiments with milch cows conducted by the Danish State agricultural experiment station. The plan of the experiment was similar to that of the preceding series (E. S. R., 4, p. 601). The experiments were conducted during 1893 and 1894 at 7 different estates with 247 and 240 cows, respectively. All the cows received the same feed during the preliminary period and the after feeding (the post-experimental period). During the experiment proper the feed of one lot of cows remained as in the preliminary period, while that of the other two lots was changed in the manner indicated by the following example: At one of the estates (Bregentoed) all cows received during the preliminary feeding and during period 2 3 lbs.[1] of mixed grain (one third barley, two thirds oats), 3 lbs. of wheat bran, 2 lbs. of oil cakes (equal parts of rape, palm nut, and sunflower-seed cake), 20 lbs. of mangel-wurzels, 6 lbs. hay, and straw *ad libitum.* During period 1 the grain feed was changed for lot A to 6 lbs. mixed grain, and for lot C to 6 lbs. of wheat bran, in both cases in the place of 3 lbs. each of grain and bran.

---

[1] Danish pounds; 1 lb. Danish=1.1 lb. avoirdupois.

At some estates there was a fourth lot (D) which received wheat shorts in the place of wheat bran, but otherwise the same as lot C. Analyses of products and of fodders fed were made as in previous experiments.

Effect on quality of milk.—The average percentages of fat for all cows included in the experiments of both years were as follows:

Average per cent of fat in milk.

Lot.	Experiments of 1893.			Experiments of 1894.			Average for both years.		
	Preliminary period.	Period 1.	Period 2.	Preliminary period.	Period 1.	Period 2.	Preliminary period.	Period 1.	Period 2.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per sent.*	*Per cent.*	*Per cent.*
A	3.13	3.09	3.27	3.04	2.99	3.25	3.09	3.04	3.26
B	3.13	3.16	3.30	3.06	3.06	3.28	3.10	3.11	3.29
C	3.12	3.14	3.28	3.09	3.10	3.30	3.10	3.12	3.29

There is no marked difference in the fat content of the milk produced by the different lots during either period of the experiment. There was a small decrease in the fat content of the milk produced by lot A during period 1, in 11 out of 14 series, over that of lot B. From period 1 to period 2 there was a similar increase in the per cent of fat in the milk produced by this lot. These differences are, however, in the author's opinion, too small to be of any practical importance.

The complete chemical analyses of the samples of milk from the different lots also failed to disclose any decided difference in the composition of the milk attributable to the different concentrated foods fed, and the author therefore concludes that "in the comparative feeding trials with milch cows now continued for 7 consecutive years at this station, in which 1,639 cows have been included (separated into 161 lots on 10 estates in different parts of our country), it has been found over and over again that the changes made in the food of the lots have had practically no influence on the chemical composition of the milk. In these experiments grain has been fed against roots, against oil cake, and against wheat bran or shorts; grain and oil cakes have been fed against roots, or roots have been fed as an additional food."

Effect on milk yield of cows.—At the beginning of the experiments the cows in lots A, B, and C had been in milk 93, 93, and 94 days, respectively, as an average for both years. The average age of the cows in lots A, B, and C was 7.7, 7.6, and 7.6 years, respectively. These two factors are of the greatest importance in determining the decrease in milk yield of a number of cows during a given period. The average daily yields of milk for each lot during the different periods were as shown below:

Average daily yield of milk per cow.

Lot.	Experiments of 1893.			Experiments of 1894.			Average for both years.		
	Preliminary period.	Period 1.	Period 2.	Preliminary period.	Period 1.	Period 2.	Preliminary period.	Period 1.	Period 2.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
A	24.7	21.3	19.0	25.8	22.4	20.6	25.3	21.9	19.8
B	24.6	21.6	19.5	25.8	22.5	21.2	25.2	22.1	20.3
C........	24.7	21.8	19.7	25.8	22.3	20.9	25.3	22.1	20.3

The results indicate a similar nutritive effect in the feeds compared with a slight increase in favor of the wheat-bran feeding. The differences found, however, are not on the average greater than what might have been found in feeding a similar number of cows the same feeding stuffs for several months.

The average live weights of the cows increased during the experiment; the increase was greater for lot B than for lot A, and greater for lot C than for lot B. The cows in lot B and C ate somewhat more straw than those in lot A, the difference being about 0.4 lb. per head daily.

Wheat shorts vs. wheat bran.—The experiments with these foods were conducted with 240 cows, 6 trials being made in all on 3 different estates each year. No appreciable difference was apparent in the effect of the foods either on the quality or the quantity of milk produced, or in change of live weight of the cows during the experiment. A small difference in favor of shorts as regards the yield of milk was found in 3 trials.—F. W. WOLL.

Record of a herd of cows at Weende, BACKHAUS (*Jour. Landw. 42, No. 3, pp. 243–281*).—This is the individual record for one year of a herd of 59 cows. Trial milkings were made weekly, and composite samples were taken for testing.

Of the 20 cows which gave over 4,000 kg. of milk during the year, 14 had a relatively short lactation period, calving during the year, while only 6 gave milk throughout the year. The results indicate that as far as the milk yield is concerned it is most advantageous to have the cows calve as often as possible. In the majority of cases the milk yield and the fat content were in inverse proportion. Usually the fat content increased as the milk yield decreased with advancing lactation; and out of the 20 cows giving over 4,000 kg. of milk only 6 gave milk with the average fat content for the herd—3.266 per cent. The percentage of solids-not-fat was usually much more uniform than that of fat. In the case of 3 cows which did not get with calf, there was no increase in the percentage of fat and solids-not-fat as they shrunk in milk, and 3 other cows tested for a short time and then sold because they did not get with calf showed a similar tendency. This suggests to the author the theory that the increase in the richness of milk with advancing lactation may follow as a result of being with calf rather than of the shrinkage in yield.

Fattening lambs, C. D. SMITH and F. B. MUMFORD (*Michigan Sta. Bul. 113, pp. 27*).—This experiment was made to compare different grain foods for lambs during winter. It included 125 grade Shropshire lambs, divided into 9 lots, which were fed in the barn from November 27 to March 12. The food was given to all *ad libitum*. It consisted of clover hay with different grain feeds, with or without roots. The rations, aside from the clover hay, are given in the following table, together with the amounts of protein and carbohydrates which the animals in each lot consumed per 1,000 lbs. live weight daily:

Character and composition of rations of lambs.

Lot.	Ration.	Nutrients fed daily per 1,000 lbs. live weight, Protein.	Nutrients fed daily per 1,000 lbs. live weight, Carbohydrates.	Nutritive ratio of food.
		Pounds.	*Pounds.*	
1	Whole corn	2.0	16.0	1:8.0
2	Whole corn and roots	2.1	16.7	1:8.0
3	4 parts corn to 1 part linseed meal, and roots	2.7	16.1	1:6.0
4	4 parts corn to 1 part linseed meal	2.8	15.7	1:5.6
5	Whole corn and wheat bran, equal parts	2.5	14.8	1:6.0
6	Whole corn and whole wheat[1]	2.1	15.5	1:7.5
7	5 parts whole wheat to 1 part linseed meal	2.7	15.0	1:5.5
8	Whole corn ("self-feed")	2.0	15.7	1:7.9
9	Whole corn and wheat bran, equal parts ("self feed")	2.6	16.1	1:6.2

[1] Proportion not stated.

The linseed meal used was new process. The roots consisted of a mixture of equal parts of ruta-bagas and sugar beets. A detailed record is given for each lot of the food eaten, gains, cost of food eaten, and the financial result. In the latter the lambs are reckoned at 3 cts. per pound at the beginning and at 3.9 cts. per pound at the close of the experiment, and no allowance is made for the value of manure or the cost of attendance. The relations of temperature to gain, of carbohydrates and protein to gain, and of temperature to the amount of dry matter required to produce a pound of gain are discussed and illustrated graphically.

A summary of the results is as follows:

Lot.	Ration.	Average weekly gain.	Dry matter fed per pound of gain.	Cost of food per pound of gain.	Average profit per lamb.
		Pounds.	*Pounds.*	*Cents.*	*Cents.*
1	Corn	2.18	7.02	4.6	51.0
2	Corn and roots	2.64	6.41	4.6	45.6
3	Corn, linseed meal, and roots	2.61	6.72	5.3	20.0
4	Corn and linseed meal	2.38	6.99	5.1	31.0
5	Corn and bran	1.78	9.13	5.3	17.0
6	Wheat and corn	1.97	7.64	5.4	31.0
7	Wheat and linseed meal	1.94	8.04	6.3	1.0
8	Corn ("self-feed")	1.65	8.57	5.7	30.0
9	Corn and bran ("self-feed")	1.58	10.03	6.8	2.0

"(1) Under the conditions existing in this experiment the lot receiving a good quality of clover hay with a grain ration of whole corn required less dry matter to produce a pound of gain, made greater gains, were in better flesh, and in general were fed at a greater profit than the lots fed corn and bran, corn and wheat, or wheat and oil meal.

"(2) Lots receiving roots in the ration required less dry matter to each pound of gain, made greater gains, and drank less water than the other lots fed the same ration without the roots.

"(3) This experiment would seem to indicate that, when the conditions are similar to those in this test, the feeding of wheat to fattening lambs is better practice than selling at the prices prevailing during this experiment.

"(4) This experiment indicates that lambs may be successfully fattened by means of a self-feed, but the gains made are produced by a greater consumption of dry matter for a pound of gain, and are consequently less profitable than gains resulting from feeding at regular intervals in the ordinary manner.

"(5) In this experiment the value of foods for fattening purposes seems to depend more upon the supply of available carbohydrates than upon the supply of protein.

"(6) Cold temperatures were favorable to increased gains and warm temperatures were very generally accompanied by decreased gains.

"(7) Less dry matter was required to produce a pound of gain in cold than in warm temperatures."

Grain feeding lambs for market, J. A. CRAIG (*Wisconsin Sta. Bul. 41, pp. 21*).—Three separate experiments are described in feeding grain to lambs before weaning, between weaning and fattening, and during the fattening period only. In the first two experiments there were 2 lots of lambs, one lot being fed grain from before weaning until the close of the fattening period, and the other lot receiving no grain until the fattening period. In the third trial there were 3 lots, the grain feeding commencing with one lot before weaning, with another after weaning, and with the third during the fattening period.

The grain fed before weaning was corn meal, wheat bran, and linseed meal; between weaning and fattening, corn and linseed meal, or whole oats; and during fattening, corn, oats, and linseed meal, or corn and linseed meal, or corn and oats. Between weaning and fattening the lambs were all pastured.

The feeding period before weaning was 10 to 12 weeks; between weaning and fattening, 14 to 19 weeks, and the fattening period, 12 to 14 weeks. At the end of each period the lambs were valued by a local butcher. In estimating the relative cost, the gain only is considered and no account taken of the pasturage. The first experiment has been already reported in the Annual Report of the station for 1892 (E. S. R., 5, p. 503). The results of the 3 experiments are tabulated in the bulletin, and are concisely stated in the following summary:

"(1) The feeding of grain before weaning produced an average of 61 cts. per head more profit at weaning time than that obtained from the lambs receiving no grain. The average value of each lamb in the lot receiving grain at $5.66 per 100 lbs. was $3.83 per head, and the average value of the grain they ate was 33 cts. per head, while the average value of the other lot not receiving grain at $4.91 per 100 lbs. was $2.89, leaving 61 cts. profit per head in favor of grain feeding. The average of the three trials shows that the grain-fed lambs before weaning required 4 lbs. of grain for each 1 lb. of gain that they made over the lambs that had no grain.

"(2) The feeding of grain after weaning to lambs that had not received any before weaning produced an average increase which slightly more than paid a good market price for the grain they ate up to the time they were to be sold in the fall. The average value of each lamb in the fall after having received grain from weaning time was $3.66 at $4 per 100 lbs., and they ate 54 cts. worth of grain per head, while the average value per head of those that had not received grain, at $3.81 per 100 lbs., was $2.96, a difference of 16 cts. in favor of the lambs fed grain since weaning. As the average of the three trials it required 6.7 lbs. of grain for the grain-fed lambs to make 1 lb. of gain more than those that had no grain.

"(3) The feeding of grain both before and after weaning produced an average of 34 cts. per head more profit if sold in the fall than that obtained from the lambs that were not fed grain. The average value in the fall of each lamb in the lots receiving grain before and after weaning, at $4.81 per 100 lbs., was $4.82, and the average cost of grain was $1.38, while at the same time those that had no grain, at $3.81 per 100 lbs., were worth an average of $3.10 per head; a difference in profit of 34 cts. per head to the credit of the lambs that received grain.

"(4) The results of the three trials show that there is no appreciable difference in the gain made during the winter fattening between the lambs that had grain previous to fattening and those that had not. The difference in the cost of gain was more marked, there being an average difference of 29 cts. per 100 lbs. in favor of those that had no grain previous to fattening. The average weekly gain per head of the lambs fed grain previously was 2.89 lbs. during the fattening, while that of the other lambs was 2.95. The average cost of 100 lbs. of gain was $4.93 in the instance of the grain-fed lambs, and $4.66 with those that had no grain before fattening started.

"(5) When the experiment was concluded and the lambs that had grain before fattening and those that had not were ready for market, the average profit from the former was 48½ cts. per head greater than from the latter. The average weight of the grain-fed lambs when sold was 140.2 lbs., and that of the others was 121.7 lbs. per head. The former brought 75 cts. per 100 lbs. more than those that had no grain before winter feeding.

"(6) The grain feeding had a marked influence on the earliness of the maturity of the lambs. In the first two trials the grain-fed lambs reached an average of 125 lbs. per head in weight 7 and 4 weeks, respectively, before the others. In these trials the average cost of this weight in the instance of the grain-fed lambs was $2.68 per head, exclusive of pasture, while in the instance of the other lambs it was $1.96 per head. This difference in cost was largely due to the heavy feeding of grain after weaning, and when this was guarded against in the third trial it was found that the average of 113.9 lbs. per head, which the lambs that had no grain reached on the conclusion of the experiment, was made 7 weeks sooner by the lambs fed grain continuously, and it was made at a slightly less cost.

"(7) There was no difference in the character of the meat in the carcasses of the lambs that had grain continuously and those that had not.

"(8) The per cent that the lambs dressed was about the same in all lots, and no marked difference was found in the weight of the different organs of the body.

"(9) The feeding of grain made all the fleeces of the lambs receiving it more compact and smoother than the others.

"(10) The grain-fed lambs sheared in the 3 trials an average of 2.2 lbs. more wool than the others.

"(11) The greater amount of wool shorn by the grain-fed lambs was to an extent due to the greater amount of yolk or oil it contained. The shrinkage in the first two trials was 5 per cent greater in the instance of the grain-fed lambs than with the others, and in the last trial it was 2 per cent greater.

"(12) The wool on the lambs that were fed grain continuously grew to a slightly greater length than it did in the fleeces of the others. In the first trial the average length of the shoulder fiber in the grain-fed lot was 5 in. as against 3.76 in the other; in the second trial, 4 in. as against 4.2 in.; and in the third it was 3.3 in. against 2.9 in. The second trial showed no appreciable difference in this particular."

Preliminary report of a feeding test with swine, E. R. LAKE (*Washington Sta. Bul. 11, pp. 31–36*).—A brief account of feeding 3 pigs for 55 days on wheat and barley chop alone or combined. The inference is drawn that barley chop alone is a more profitable feed than wheat alone at approximately the same price, and that barley and wheat mixed in the proportion of 1 to 2 is better than either alone.

Comparative investigations of rye spoiled by storing in elevators, and the bread baked from the same, THAL (*Pharm. Ztschr. Russland, 33, pp. 641–646; abs. in Chem. Centbl., 1894, II, No. 25, p. 1002*).

The use of salt as a cattle food, B. ROST (*Molk. Ztg., 8 (1894), No. 52, p. 803*).

Food stuffs for domestic animals in times of drought, N. BOCHICCHIO (*Staz. Sper. Agr. Ital., 27 (1894), No. 20, pp. 386–399*).

Analyses of fodder articles, C. A. GOESSMANN (*Massachusetts State Sta. Bul. 56, pp. 4–7*).—This includes tabulated analyses (food and in most cases fertilizing constituents) of 23 samples of feeding stuffs, including cotton-seed meal (decorticated and undecorticated), cotton-seed bran, gluten meals, and feeds of different kinds, oil cake, peanut cake, peanut husks, peanut feed, and meat meal.

Stock feeding in Illinois, G. E. MORROW (*Illinois Sta. Bul. 36, pp. 421–431*).—Replies to a circular letter were received from 108 feeders in different parts of the State in regard to feeding cattle, pigs, and sheep. These embody much practical information of interest and value, and are summarized in the bulletin. In addition the practical deductions from experiments on various phases of stock feeding, covering a number of years, are summarized.

Stock feeding, G. L. TELLER (*Arkansas Sta. Bul. 30, pp. 137–170*).—This is a popular bulletin on the subject of feeding, including information on the composition of feeding stuffs, the principles of feeding, feeding standards, calculation of rations, and tables showing the digestible nutrients in a number of feeding stuffs.

Tests of dairy cows at experiment stations, E. HITCHCOCK (*Cult. and Country Gent., 1894, Jan. 31, p. 92*).—A criticism of methods.

Cost of milk production, H. H. WING (*New York Cornell Sta. Rpt. 1893, pp. 69–95, pls. 2, figs. 4*).—A reprint from Bulletin 52 of the station (E. S. R., 4, p. 936).

Peanut oil as a food supplementary to skim milk in calf feeding, M. PETERSEN (*Fühling's landw. Ztg., 44 (1895), No. 1, pp. 13–17*).

VETERINARY SCIENCE AND PRACTICE.

Bovine tuberculosis, J. L. HILLS and F. A. RICH (*Vermont Sta. Bul. 42, pp. 70*).

Synopsis.—The subjects treated are the following: A detailed account of a tuberculin test of the station herd; the prevalence of tuberculosis in the State; a general discussion of the tubercle bacillus, of sources of infection, and of conditions favoring the development of tuberculosis; a brief description of the symptoms and lesions of the disease; a general discussion of the tuberculin test and of the objections sometimes urged against it; the interrelation of human and bovine tuberculosis; methods of sterilizing or pasteurizing milk; means of preventing the spread of tuberculosis, and the relation of the State toward this disease.

Thirty three animals in the station herd, most of them milch cows, were tested with tuberculin one or more times. In 24 instances there were reactions. *Post-mortem* examinations confirmed the test throughout. The distribution of the disease was as follows: Lungs, bronchial and postpharyngeal glands, 90 per cent; udder and supermammary glands, 73 per cent; and intestinal and mesenteric glands, 50 per cent.

Of 786 Vermont cattle tested with tuberculin by the station veterinarian, 138 were tuberculous. Omitting the station herd and one other large herd in which five sixths of the animals were diseased, there were 39 tuberculous animals out of a total of 662. The proportion of tuberculous cattle in the State, however, is regarded as less than these figures would seem to indicate, for the herds in which the tests were made were those in which the presence of the disease was suspected.

In ascertaining the normal temperature of the animals tested, it was found convenient in some cases to determine this several days after the injection of the tuberculin was made.

The authors advise caution in the interpretation of tuberculin tests made on a 2-year-old with her first calf, as the first gestation renders the system highly susceptible to any excitement.

> "It has been claimed that animals suffering from actinomycosis may react to tuberculin. From a practical standpoint, since lumpy jaw is contagious and communicated to man, this makes little difference, yet it is not impossible that there may have been tubercular lesions overlooked in these cases. One of us had 2 cases of this kind. One cow with lumpy jaw gave no reaction whatever to tuberculin; another, with both tuberculosis and lumpy jaw, gave the highest reaction (108.6°) yet obtained."

In over 1,000 cases injected there were found only 2 cases of nonreacting tuberculous cattle. Old cows responded less readily than other animals to the usual dose of tuberculin. In the author's experience no injurious effect has followed the use of tuberculin on healthy animals.

> "It is already claimed that other materials will cause the same febrile reaction. Taurin and kreatin (Merck's) have given good results in the hands of Dr. W. L. Zuill, of Philadelphia, and E. Centanni claims that 'it has been proved that identically the same action as that of tuberculin can be produced by the injection of the extracts or other products of various bacteria, even such as are known to have no pathogenic (disease-producing) properties.' . . .
>
> "The aggravation of the disease in tuberculous animals is not a valid argument in cases where such as react are promptly killed. No one who expects to keep his mild cases should permit its use, for it only makes a bad matter worse."

The bulletin contains data relative to the attitude toward tuberculosis of the boards having control of the live stock interests of Ontario, Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Pennsylvania, Maryland, Ohio, Indiana, Illinois, Tennessee, Michigan, Minnesota, Kansas, Colorado, Oregon, and Missouri.

Hog cholera and swine plague, D. E. SALMON (*U. S. Dept. Agr. Farmers' Bul. 24, pp. 15*).—This bulletin, prepared in the Bureau of Animal Industry, treats of the symptoms, *post-mortem* appearance, causes, treatment, and sanitary measures for the prevention of hog cholera and swine plague. Experiments made during the past year indicate that the treatment of these diseases may be successful.

"The most efficacious formula which has been tried is the following:

	Pounds.
Wood charcoal	1
Sulphur	1
Sodium chlorid	2
Sodium bicarbonate	2
Sodium hyposulphite	2
Sodium sulphate	1
Antimony sulphid	1

"These ingredients should be completely pulverized and thoroughly mixed.

"The dose of this mixture is a large tablespoonful for each 200 lbs. weight of hogs to be treated, and it should be given only once a day. When hogs are affected with these diseases they should not be fed on corn alone, but they should have at least once a day soft feed, made by mixing bran and middlings, or middlings and corn meal, or ground oats and corn, or crushed wheat with hot water, and then stirring into this the proper quantity of the medicine. Hogs are fond of this mixture; it increases their appetite, and when they once taste of food with which it has been mixed they will eat it, though nothing else would tempt them.

"Animals that are very sick and that will not come to the feed should be drenched with the medicine shaken up with water. Great care should be exercised in drenching hogs or they will be suffocated. Do not turn the hog on its back to drench it, but pull the cheek away from the teeth so as to form a pouch, into which the medicine may be slowly poured. It will flow from the cheek into the mouth, and when the hog finds out what it is it will stop squealing and swallow."

An inquiry into the alleged relation existing between the Burrill disease of corn and the so-called cornstalk disease of cattle, V. A. MOORE (*Agl. Sci., 8 (1894), No. 6–9, pp. 368–385*).—The author's conclusions are as follows:

"(1) There is no species of bacteria or other microörganism which can be demonstrated by microscopic examination, or by ordinary bacteriological methods, constantly present in the organs or blood of cattle dying late in the fall or early winter of the so-called cornstalk disease.

"(2) The disease of corn described by Professor Burrill in the mature plant is widely distributed. Its lesions are usually associated with a single species of bacteria (*Bacillus cloacæ*).

"(3) Full-grown cornstalks affected with the corn blight have no ill effect upon cattle feeding exclusively upon them, neither do they produce a bacterial disease in rabbits.

"(4) The dwarfed cornstalks are harmless to rabbits. This form of the Burrill disease is presumably due to causes other than bacteria.

"(5) Pure cultures of the bacillus found in the lesions of the diseased corn, and supposed to be their cause, have no pathogenic effect on experimental animals, excepting when excessively large quantities are injected into the circulation.

"(6) The bacillus first described by Professor Burrill, and isolated by him from the lesions in the diseased corn, belongs to the *Bacillus cloacæ* group of bacteria, which is widely distributed in nature. This group of organisms is not known to be possessed of any marked economic importance.

"(7) There is no clinical or experimental evidence sufficient to show that the Burrill disease of corn is responsible for any disease in animals. There are, on the contrary, many facts to support the assumption that there is no causal relation whatover existing between this malady and the so-called cornstalk disease of cattle."

The horse's teeth, E. P. NILES (*Virginia Sta. Bul. 36, pp. 7*).—This consists of a statement concerning the age at which the different temporary teeth are replaced and a general discussion of the symptoms attributable to defects of the teeth in colts and mature horses. None of the operations intended to remedy defects of the teeth are described.

Dehorning, I. P. ROBERTS (*New York Cornell Sta. Rpt. 1893, pp. 129–143, figs. 3*).—A reprint of Bulletin 54 of the station (E. S. R, 5, p. 204).

Losses following vaccination against anthrax, J. McFADYEAN (*Jour. Roy. Agr. Soc. England, 3d ser., 5 (1894), No. 20, pp. 800–807*).

Researches on the production of the charbon bacillus without spores, H. SURMONT and E. ARNOULD (*Ann. Inst. Pasteur, 8 (1894), No. 12, pp. 817–832*).

Investigations of bovine tuberculosis in New York State (*New York State Bd. Health, Fourteenth An. Rpt., vol. 2, p. 510*).—This consists of tabulated data giving in detail the statistics of herds examined and notes on *post-mortem* examinations of animals slaughtered.

The suppression of bovine tuberculosis and glanders, F. L. RUSSELL (*Maine Sta. Bul. 13, 2d ser., pp. 7*).—This bulletin consists of a general discussion of tuberculosis and glanders, and a statement of the diagnostic value of turberculin and mallein.

Contribution to the knowledge of the streptococci of yellow "galt," L. ADAMETZ (*Jour. Landw., 42, No. 3, pp. 231–241*).—A study of the microörganisms occuring in the milk of cows affected with a form of udder inflammation common in Switzerland under the name of *gelbe galt*.

DAIRYING.

Contribution to the study of the colostrum of the cow, V. HOUDET (*Ann. Inst. Pasteur, 8 (1894), No. 7, pp. 506–513*).—As first pointed out by Lassaigne[1] the formation of colostrum proper is preceded by the secretion of an albuminous liquid which sometimes begins to form 2 months before parturition. This secretion often appears under 2 forms—a brownish, viscous, honey-like product, and a lemon-yellow, non-viscous liquid, although the two are not always distinct and often coexist in the same animal, the earlier milkings furnishing the first, the later milkings the second. Examinations of samples of the viscous secretion showed it to be curdled by heating and precipitated by acetic acid, bichlorid of mercury, and alcohol, but not curdled by rennet. It was absolutely free from fat, and it contained traces of mineral matter, 63.14 per cent of water, 22.74 per cent of albuminoids soluble in water (to the extent of passing a Chamberland filter), and 14.12 per cent of albuminoids insoluble in water. The fluid secretion contained less water and less soluble albuminoids than the viscous secretion, and gave a barely appreciable precipitate with bichlorid of mercury and alcohol, but behaved in the same manner as the latter

[1] Ann. Phys. et Chim., 1837, 1841.

toward heat, acetic acid, and rennet. One hundred cubic centimeters of it contained the following amounts of dry matter:

Composition of fluid secretion preceding colostrum.

	In suspension.	In solution.
	Grams.	*Grams.*
Fat	0.15	
Lactose		0.80
Albuminoid matter	4.39	1.38
Phosphate of lime	0.03	0.08
Other salts	0.14	0.24
Solids	7.21	

The composition of the fluid colostrum is thus seen to more nearly approach that of milk. Four or five days before parturition this secretion disappears entirely and is replaced by colostrum proper.

True colostrum is described as an opaque, yellow liquid of pungent taste. Sometimes it is of brick-dust or reddish color, due to the presence of blood. Its reaction is not well defined, being sometimes acid, sometimes alkaline, and sometimes amphotere. Churning colostrum for 1½ hours gave no butter, but in a centrifugal separator a yellow butter-like product was obtained. It is curdled by heat, acetic acid, bichlorid of mercury, and rennet. The more nearly its composition approached that of normal milk the less easily it curdled on heating and the less marked its color became. The following table shows the composition (100 cc.) of the colostrum of a Norman cow 6 days before calving (true colostrum just beginning to form), 4 days before calving, and immediately after calving:

Composition of colostrum at different stages.

	Six days before calving.		Four days before calving.		Just after calving.	
	In suspension.	Soluble.	In suspension.	Soluble.	In suspension.	Soluble.
	Grams.	*Grams.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*
Fat	0.50		3.01		3.14	
Lactose		2.35		3.17		2.70
Albuminoids	17.43	0.47	12.08	0.45	14.53	0.25
Phosphate of lime	0.33	0.11	0.37	0.10	0.35	0.11
Mineral salts	0.28	0.08	0.25	0.15	0.28	0.14
Solids	21.45		19.58		21.50	

These figures show a sudden increase in the amount of albuminoids over that contained in the fluid colostrum already reported (6.77 gm.). This may be due to a diversion to the udder of the nutritive material which up to this time had been supplied to the fetus and its connections. An increase in fat and phosphates and a decrease of soluble albuminoids will also be observed.

The following analyses of colostrum from a Norman cow which calved November 12 illustrate different stages of the transition of colostrum into normal milk:

Composition of colostrum at different dates.

	Fat.	Lactose.	Albuminoids.	Phosphate of lime.	Mineral salts.	Total solids.
	Grams.	*Grams.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*

Analyses of colostrum from cows of other breeds are reported, confirming in general the above results.

The author concludes that after parturition the dry matter of colostrum decreases, then about the third day increases, and afterwards drops to the normal figure for milk. The quantity of fat is subject to great oscillations. The increase in milk sugar is gradual. The albuminoid matter exists both in suspension and in solution; both forms decrease after birth, the suspended albuminoids much more than the dissolved albuminoids. The phosphate of lime and other salts are abundant at first; 5 days after parturition their quantity is normal. By this time, in fact, the colostrum has gradually become normal in color and in its chemical composition and behavior toward rennet very similar to normal milk.

In conclusion, it is suggested that the changes in colostrum are the result of efforts of nature to adapt the food supply to the varying requirements of the young in the early stages of its life, the colostrum acting first probably as a purgative to remove from the intestines of the young animal the meconium which has accumulated during gestation.

On the composition of the milk of various animals, A. PIZZI (*Staz. Sper. Agr. Ital., 26 (1894), No. 6, pp. 615–639*).—Studies are reported on human milk and the milk of the goat, sheep, buffalo, mare, ass, rabbit, sow, dog, cat, and rat. All of the animals used had given birth to their young 12 to 40 days before the sample of milk was drawn. Butter was made from human milk and from the milk of the goat, sheep, buffalo, and sow. The melting point, point of solidification, and volatile fatty acids (Wollny's numbers) of the butters were as follows:

Examination of butter from different kinds of milk.

Butter made from—	Melting point.	Point of solidification.	Volatile fatty acids (Wollny).
	Deg. C.	*Deg. C.*	
Human milk	32.0	22	1.42
Goat's milk	36.5	31	28.60
Sheep's milk	29–30.0	12	32.89
Buffalo's milk	38.0	29	26.18
Sow's milk	28.0	12	1.65

Owing to insufficient supply of milk, butter was not made from the milk of the other animals, but the fat was extracted from the milk by ether and the volatile acids determined in this. Mare's milk was distinctly alkaline, and Wollny's number for the fat was 11.22. Ass's milk gave a distinct reaction with red litmus paper, and Wollny's number was 13.09. Wollny's number for the fat of the milk of the rabbit was 16.06, the dog 1.21, the cat 4.40, and the rat 2.97. Sow's milk was quite alkaline, as was also that of the cat. The following table gives the composition of the milk of the buffalo and the rabbit:

Composition of buffalo's and rabbit's milk.

	Milk of buffalo.	Milk of rabbit.
	Per cent.	*Per cent.*
Water	82.2090	69.5000
Fat	7.9500	10.4500
Albuminoids	4.1300	15.5400
Sugar	4.7500	1.9500
Ash	0.9700	2.5600
Specific gravity at 15° C	1.0332	1.0493

A microscopical examination was made of the milk of the 12 kinds of animals named above, and it was found that the fat globules were largest in the milk of the rabbit and the mouse. The globules were smallest in the milk of the sow, ass, and mare. The milk of 4 cows was examined just before parturition and at different stages after calving. Three to 6 hours before parturition Wollny's numbers for the colostrum fat were 4.40 to 4.73, 6 hours after calving 6.16 to 6.27. After this time the volatile fatty acids rapidly increased, reaching in one instance 28.16 at 114 hours after calving, in another case 28.93 in 108 hours, in another reaching 29.81 at 60 hours, and in another being only 24.75 after 189 hours.

On tubercle bacilli in milk, K. ARNELL (*Kgl. Landt. Akad. Handl. Tidskr., 33 (1894), pp. 239–243*).—The author gives an account of the methods proposed by Ilkewitsch, Thörner, and Asessi, for the examination of milk for tubercle bacilli, and recommends the following method as reliable: The milk is treated according to the Gottlieb-Röse method,[1] ammonia is added, and then alcohol, ether, and benzin; the lower layer forming under the clear ethereal solution contains all bacteria found in the milk. The layer is transferred to a conical, heavy glass tube, 10 cm. long, holding about 10 cc., and is placed in a metal cover fitting into the holes of the lactocrite disks and whirled. The residue forming at the sharp point of the tube is examined under the microscope for tubercle bacilli.—F. W. WOLL.

Water content of Schleswig-Holstein butter, O. HENZHOLD (*Milch Ztg., 23 (1894), No. 43, pp. 684, 685*).—The study of the water content of butter in Schleswig-Holstein, which was made by the experiment station at Kiel at the request of the Prussian Minister of Agriculture (E. S. R., 5, p. 952), included samples from private dairies and coöperative creameries in different parts of the province and from the station creamery, made in nearly every month of the year. In all, 101 samples were examined.[2] The 23 samples of dairy butter contained from 7.82 to 19.26 per cent of water, and averaged 12.77; and the 26 samples of creamery butter contained from 11.07 to 17.57, and averaged 13.66 per cent.

In order to observe the variations under normal conditions, 37 samples of butter were made by students in the Kiel dairy school, the water content being noted of the butter as taken from the churn, when worked once, and when salted and worked twice. This ranged for the finished butter from 5.90 to 16.81, and averaged 11.70 per cent. The butter was all made by approved methods, so that the difference in water content is believed to be due to the difference in makers, especially in working. In spring and summer the cream was churned at 10 to 12° C. (50 to 53.6° F.), and in fall and winter at 13 to 16° C. (55.4 to 60.8° F.).

In 15 other trials the effect on the water content of churning at too high a temperature or of overchurning was studied. The results follow:

Water content of butter churned and treated differently.

No. of sample.	Churning.			Water content of butter.			Remarks.
	Temperature.	End temperature.	Time.	As taken from churn.	Worked once (unsalted).	Worked twice and salted.	
	Deg. C.	*Deg. C.*	*Min.*	*Per cent.*	*Per cent.*	*Per cent.*	
1	12.0	13.5	29	21.48	18.93	15.08	Gathered for 3 minutes.
2	12.0	14.0	25	24.07	19.26	15.83	Gathered for 5 minutes.
3	12.0	13.5	30	21.77	20.45	15.30	Gathered for 3 minutes.
4	14.5	15.0	26	17.48	13.01	11.41	Do
5	15.0	17.0	22	17.77	14.98	13.41	
6	17.0	18.5	17	19.91	15.00	11.79	
7	17.0	18.5	22	29.56	29.18	18.32	
8	17.0	19.0	20	19.65	17.54	13.29	
9	17.0	18.0	30	18.66	15.93	12.25	
10	12.0	14.0	25	17.68	15.76	13.22	Butter left 2 days on ice.
11	14.0	15.0	25	16.38	15.05	13.31	Do

---

[1] Landw. Vers. Stat., 40, pp. 1–27.

[2] The water was determined by heating 10 to 12 gm. of butter in a porcelain dish with 20 gm. of broken pumice stone, as described by the author in Milch Ztg., 20 (1891), p. 71.

Water content of butter churned and treated differently—Continued.

No. of sample.	Churning.			Water content of butter.			Remarks.
	Temperature.	End temperature.	Time.	As taken from churn.	Worked once (unsalted).	Worked twice and salted.	
	Deg. C.	*Deg. C.*	*Min.*	*Per cent.*	*Per cent.*	*Per cent.*	
12				19.47	13.56	11.07	Churned at ordinary temperature.
13	20.0			27.67	24.38	18.08	Same cream as No. 12.
14				17.64	14.09	11.43	Milk separated at 35° C.; churning normal.
15				22.65	16.00	12.08	Churning normal; fresh butter kept in water at 25° C. for 18 hours.

The average water content, 13.73 per cent, was only 2 per cent higher than the average where the conditions were normal.

In the 101 samples the range was 5.90 to 19.26 and the average 12.96 per cent. Of the whole number, 13 per cent had over 15 per cent of water and 5 per cent had over 16 per cent.

The water content of East Prussian butter, R. EICHLOFF (*Milch Ztg., 23 (1894), No. 46, pp. 733, 734*).—From February, 1893, to October, 1894, an investigation was made of this subject by the dairy experiment station at Kleinhof-Tapiau, with the following results:

Water content of butter from different sources.

Butter.	Number of samples.	Minimum.	Maximum.	Average.
		Per cent.	*Per cent.*	*Per cent.*
Kleinhof Tapiau creamery	36	8.52	15.34	13.29
Other creameries	6	10.66	13.37	11.95
Peasant butter	24	10.95	26.19	[1] 14.49

[1] In striking the averages all samples with over 20 per cent of water were excluded, "as it was assumed that either the churning took place under abnormal conditions or water had been purposely worked into the butter." As one fourth of the peasant butter had 20 per cent or over, the above average is not correct.

In addition to the above, the water was determined in unworked butter and in salted and unsalted butter worked once, with the following average results:

	Per ct. water.
Unworked butter	19.41
Worked once, unsalted	14.65
Worked once, salted	13.96
Ready for market	13.15

The loss of water in keeping butter packed in closed tubs in a cellar is shown as follows:

	Per cent.
Water in fresh butter	13.15
Water in butter 1 month old	12.08
Water in butter 4 months old	6.69

A sample of whey butter had 14.05 per cent of water.

Experiments in churning cream soured with hydrochloric acid, H. TIEMANN (*Milch Ztg., 23 (1894), No. 44, pp. 701, 702*).—Experiments with this method have been reported (E. S. R., 6, pp. 248, 249). Twenty one trials were made by the author at the request of Dr. Weigmann. The cooled separator cream was run into the churn and mixed with hydrochloric acid until the desired acidity for churning was obtained. The acid was made by diluting 1 part of pure acid of 1.124 sp. gr. with 2 parts of water. The water content of the butter worked once ranged from 13.31 to 17.42 per cent, and of the butter ready for market from 12.18 to 13.76 and averaged 12.65 per cent. The fat content of the buttermilk (undiluted) ranged from 0.45 to 1.02 per cent and averaged 0.76. This buttermilk could not be sold, so the acid was neutralized with bicarbonate of soda, 6 per cent of "common acid" (starter?) added, and after standing 24 hours run through the churn again. This buttermilk sold readily.

The butter had no aroma. The taste was pronounced "fair" to "good," but there was usually a slight aftertaste, and the butter was more or less oily. Some of the samples were entered at the butter exhibition in Hamburg when from 3 to 9 days old. They were pronounced by the judges from "medium" to "fairly good," although here the absence of aroma and the oiliness were mentioned.

Trials in which a strong acid was used were not satisfactory, as a disagreeable odor was developed.

Experiments in churning cream soured with hydrochloric acid, TAMM (*Milch Ztg., 23 (1894), No. 47, pp. 750, 751*).—A practical trial lasting 2 weeks was made of this method at a creamery. After some experiments an acidity of 12 to 13° (Soxhlet's), brought about by adding 5.5 cc. of hydrochloric acid per kilogram of cream, was adopted. The fat in the buttermilk ranged from 0.37 to 0.65 per cent. In all but 2 cases the butter was normal; it had a pure, clean taste, and had not changed in 14 days, but it had no aroma. It contained 2 to 3 per cent more water than butter made as ordinarily. No free hydrochloric acid was found. The author believes the method has advantages, but is not ready to recommend its general adoption until further trials have been made, which will follow with the aid of a pasteurizing apparatus.

On the vegetable cheese, "natto," K. YABE (*College Agr., Tokyo, Japan, Bul., vol. 2, No. 2, pp. 68–72*).—The author states that since remote times there has been prepared in Japan a sort of vegetable cheese called "natto," from the seeds of the soja bean. "The beans are first boiled in water for 5 hours to render them exceedingly soft. The still hot mass is in small portions wrapped in straw and the bundles thus formed, well tied at both ends, are then placed in a cellar, in the middle of which a fire is kindled, whereupon the cellar is well closed. The heat is left to act for 24 hours, after which the product is ready for consumption."

The author has found 4 kinds of bacteria in this cheese, and has studied the changes which they induce in the nitrogenous compounds in making the cheese. Considerable peptone, and also leucin and tyrosin were found, which are believed to be undoubtedly the result of bacterial action, and xanthin and hypoxanthin, which "probably were originally present in the soja bean." In conclusion the percentage of the different nitrogenous compounds in the beans and the natto is given as follows:

Nitrogenous compounds in soja bean and vegetable cheese.

	In soja bean.	In natto from same soja bean.
	Per cent.	*Per cent.*
Total nitrogen	7.355	7.542
Nitrogen in proteids (excluding peptone)	6.899	4.033
Nitrogen in amids	0.128	1.892
Nitrogen in peptone	0.328	1.617

Determination of the degree of ripeness and the fat content of cheese, C. VON MUZAKÖZY (*Ztschr. Nahr. Untersuch. und Hyg., 8, pp. 266–268; abs. in Chem. Centbl., 1894, II, No. 20, p. 851*).—The ripening of cheese, according to the author, consists principally in that a part of the casein which is insoluble in dilute acids changes to a soluble form. The digestibility of cheese has a direct connection with this solubility of the albuminoids. The disturbances from eating overripe cheese are due, he states, to the fat of the digestive fluids becoming saturated with soluble protein compounds. Hence he proposes to determine the ripeness of cheese by the amount of soluble albuminoids. To this end the broken up cheese, extracted of fat and dried, is used for determining ash and milk sugar, and another portion is washed on a tared filter with 0.5 per cent acetic acid, and the residue and its ash determined. From this the amount of soluble albuminoids is calculated. The fat is determined, according to Soxhlet's aërometric method, by treating 25 gm. of finely grated cheese with 160 cc. of water, 25 cc. of potassium hydrate, and 60 cc. of ether, and then proceeding as with milk.

The greening of Lombardy cheese and the cleaning of copper utensils, SARTORI (*Abs. in Milch Ztg., 23 (1894), No. 44, pp. 703, 704*).—Additional proof that the greening of cheese is due to the use of copper utensils which are brightly scoured with sand. Green cheese is said to sometimes contain 100 to 110 mg. of copper per kilogram, while the average is 22 mg. The copper is said to be in the form of hydrocarbonate (verdigris). When the vessels are not scoured with sand, but are scalded out with water an oxid soon forms which protects the copper, and not enough is dissolved to color the cheese. In some factories this has been adopted instead of scouring.

Biochemic investigations of ropy milk, N. BOCHICCHIO (*Staz. Sper. Agr. Ital., 27 (1894), No. 4, pp. 339–368*).—This is largely a study of *Bacterium hesii* and *Micrococcus freudenreichii* and of their effect on various solutions.

A convenient milk sampling tube, M. A. SCOVELL (*Agl. Sci., 8 (1894), No. 6–9, pp. 355, 361*).—The apparatus consists of a long copper tube about three fourths inch in diameter, sliding into a cap closed at the lower end. This cap has 3 elliptical openings in the sides. In taking the sample the cap is drawn partly off so that the apertures are opened. The tube is then inserted in a can of milk and the inner tube pushed down into the cap, closing it, and holding a column of milk.

This tube was used in connection with the test of breeds at the World's Fair. Tables are given showing its accuracy. It is claimed that the tube will take a fair average sample of the milk as milked from the cow without mixing, even after standing some time.

A review of the bacteriology of cheese, N. BOCHICCHIO (*Staz. Sper. Agr. Ital., 27 (1894), No. 4, pp. 434–445*).

Ventilation of cheese cellars, W. HELM (*Milch Ztg., 23 (1894), No. 50, pp. 795, 796; No. 51, pp. 813–815; No. 52, pp. 828, 829; also Molk. Ztg., 8 (1894), No. 50, pp. 765–767; No. 51, pp. 785, 786*).

AGRICULTURAL ENGINEERING.

Massachusetts College barns (*Massachusetts Agl. Col. Rpt. 1894, pp. 44–51*).—The new farm buildings of the Massachusetts Agricultural College, recently completed at a cost of about $35,000, consist of a horse barn, 41 by 91 ft., and a large storage and cattle barn. These buildings are frame with steel roofing, are lighted by electricity, and were constructed with special reference to the welfare of the animals and the saving of labor in feeding the stock and handling the manure.

The main part of the cattle barn is 141 by 61 ft., and consists of a basement and two stories. The topographical condition of the site allowed a driveway of an easy grade to be constructed at the east end, leading to the upper floor, 22 ft. above the main floor. This enables the storage of hay, silage, grain, stable absorbents, and bedding with the minimum amount of labor. At the western end 20 ft. of the loft is floored over so that wagons can be turned around and driven out by the east door, as the floor at the west end is 31 ft. above the ground.

On the right of the interior driveway, which is 14 ft. wide, are traps communicating with large bins for grain, a set of Fairbanks hay scales, and ample space for the operation of heavy barn machinery, where are placed a 15-horsepower electric motor, silage cutter, cornsheller, grain mill, thresher, etc. Further on are 3 silos which extend to the basement and will hold 425 tons of silage. The rest of that side, together with nearly all of the space on the left of the driveway, is occupied by haymows, in which 240 tons of hay can be stored.

The folding door shown on the south side near the east end, opposite which is a similar door, is approached by a very easy-graded driveway held by a curved retaining wall, and admits to a floor 11 ft. wide and 12 ft. above the main floor. Below this cross floor is a very capacious vegetable cellar, reached by traps in the cross floor and through a door on the main floor. From this driveway access is also had to the second floor of the granary. When not otherwise in use this cross floor is occupied by carts, wagons, etc. The main basement is also used for the storage of implements and machinery.

Inspection of the photograph and plan will give an idea of the arrangement of the cow stable, which is 135½ by 43 ft., but there are several features that should be specially mentioned. The roof is of steel, under which is building paper and boards, then a 6 in. air space, then building paper and matched boards, then an inch and a half air space and then lath and plaster. All the ceilings and the wall of the monitor roof are of adamant cement, painted, and the walls of the stable are of matched North Carolina pine sheathing, oiled. There is no basement, and the cement passages and gutters are built upon solid earth and masonry. The gutters behind the cows incline toward the center, where they empty into cisterns on either side of the building, thus saving all the liquid manure. By making the floor of the sheds at the south end 9 ft. below that of the stable it is convenient to carry all the solid manure in barrows and dump into carts or manure spreaders for immediate distribution. The stalls, of which there are 65, are fitted with a V-shaped cement feed and water trough, provided with movable dividing frames to permit of thorough cleansing.

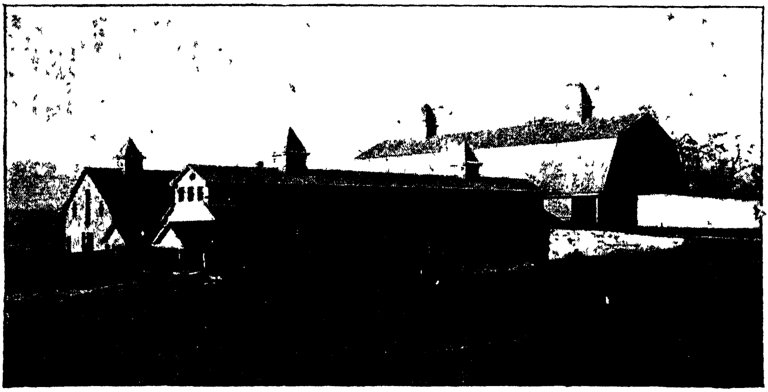

FIG. 1.—Exterior of Massachusetts College stock barn.

Stanchions of various patterns are used in the stalls, but most of the animals are fastened with the Walters tie, arranged so that each animal may be liberated separately or entire sections at once by a single motion of the lever.

The upper windows are hinged at the bottom and moved by Ormsby's ventilating apparatus, the upper sashes of the lower windows being hinged at the bottom and moved individually by transom lifts, and the lower sashes are protected by iron gratings and slide into the partitions. Trapdoors, moved by cords and pulleys, are also placed in the cupolas. This arrangement secures perfect ventilation without draft on the animals. There is 1,233 cu. ft. of air space for each animal kept in this building.

The arrangement of doors is such that hay, silage, grain, absorbents, etc., are conveniently brought from the main floor of the storage barn on trucks, and green food can be brought in on wagons through the south door.

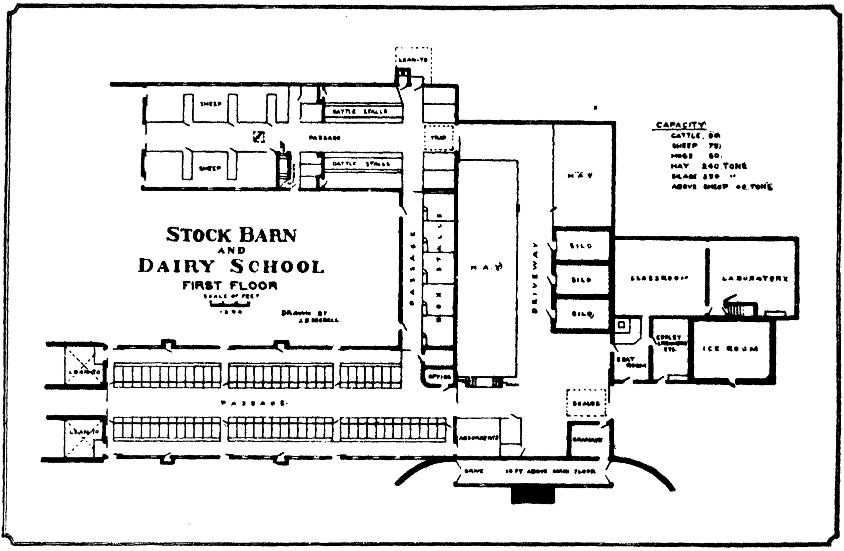

FIG. 2.—Ground plan of Massachusetts College stock barn—first floor.

A sheep barn 121 by 41 ft. is connected with the cow barn by a lean-to containing a passage and 5 box stalls fitted with plank mangers and Buckley's self-feeding watering devices. This barn contains 2 large and 5 small pens, sufficient for 75 sheep, stalls for 20 young cattle, and 4 stalls for bulls on the main floor; pigpens, slaughter room, root cellar, and swill room in the basement; and a loft large enough for 40 tons of hay. Doors open at the south end into dry and sheltered yards. The large sheep pens are provided with Hall's patent sheep racks. The cattle stalls are arranged like those in the other stable, except there are troughs of plank which have permanent partitions. The entire basement has a solid cement floor, which in the pigpens slopes to the center, where there are half-round gutters for carrying all the excreta to pits. About half of each pen has a raised plank floor, and the gutters are covered with hinged plank.

Ventilation is secured by similar devices to those used in the cow stables. Reference to the above plan and that on page 677 will show that the arrangement of doors and passages is such as to permit the passage of wagons on both basement and main floors.

The basement and one story northern extension (63 by 56 ft.) are devoted to dairy purposes. In the basement are boiler room, with 100-horsepower boiler which supplies steam and hot water for all purposes; engine room, in which there is a 75-horsepower engine, supplying power to run the 616-candlepower alternator and 416-candlepower generator; ice room, holding 300 tons of ice; and separator and churn rooms.

On the main floor are a class room, laboratory, coat room, and upper part of ice room. The dynamos furnish electricity for lighting the farm buildings and the central college buildings, and for operating the large motor in the barn and the 7½-horsepower motor in the separator room, which is used for driving all dairy machinery. Sinks with hot and cold water and steam are in all parts of this building. The class room and laboratory are of ample size, well lighted and ventilated, and are well adapted to instruction in all branches of dairy work, including chemical and microscopic examination of milk and its products.

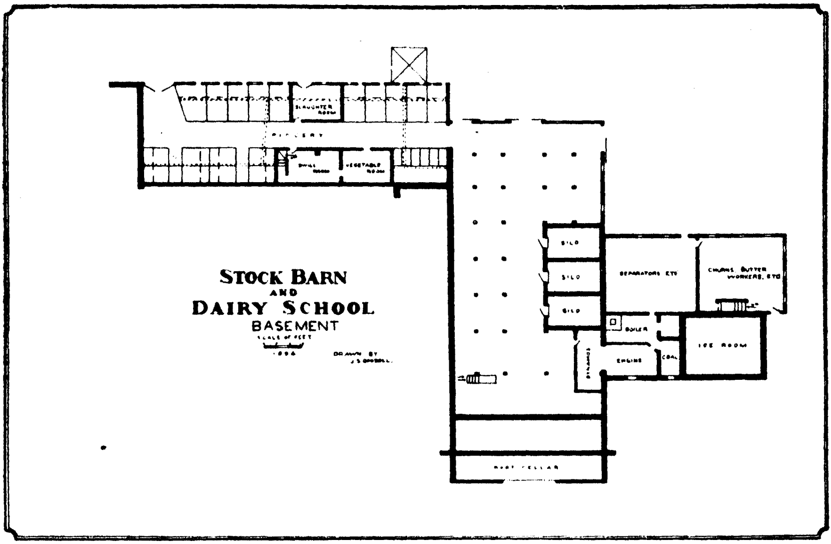

FIG. 3.—Ground plan of Massachusetts College stock barn—basement.

Proceedings of the National Road Conference, Asbury Park, New Jersey, July 5 and 6, 1894 (*U. S. Dept. Agr., Office of Road Inquiry Bul. 10, pp. 63, figs. 3*).—An account of proceedings, including the text of the various resolutions passed and addresses delivered by representatives from different States.

Roads and road making, D. O. NOURSE (*Virginia Sta. Bul. 34, pp. 137–139*).—Brief and simple directions for the improvement of dirt roads.

STATISTICS.

Annual Report of Florida Station (*Florida Sta. Bul. 24, pp. 31*).—Short reports by the director and heads of the several departments and substations, some of which are mentioned elsewhere.

Sixth Annual Report of New York Cornell Station (*New York Cornell Sta. Rpt. 1893, pp. 365*).—This includes a brief report by the director and members of the station staff, the treasurer's report for the fiscal year ending June 30, 1893, including a detailed statement of the receipts and expenditures, and reprints of the bulletins of the year.

Sundry investigations of the year (*New York Cornell Sta. Rpt. 1893, pp. 303–345, figs. 20*).—A reprint of Bulletin 61 of the station (E. S. R., 5, pp. 862, 867, 874, 879, and 883).

Imports of corn into Europe (*U. S. Dept. Agr., Division of Records and Editing Circular 147*).

NOTES.

ARIZONA STATION.—New substations have been established at Mesa and Yuma, the former in a block of 10 acres provided by the city, the latter upon a tract of land belonging to the Territorial prison. The prisoners will perform the labor required at Yuma.

MISSISSIPPI STATION.—The station has recently used the tuberculin test on a herd of 62 cows, mostly grade Jerseys, belonging to the agricultural college. Not a single suspicious case was found, the greatest rise in temperature being only 1 degree. Arrangements have been made for continuing the work with other herds in order to ascertain what foundation, if any, exists for the claim so often made by Southern stock breeders that cows raised in the South are less liable to tuberculosis than those grown in the North.

NEW HAMPSHIRE STATION.—Owing to the resignation of Professor Whitcher and Professor Wood and the burning of the farm barn, it will be necessary both to reorganize and to reequip the agricultural department.

PENNSYLVANIA STATION.—J. W. Fields, assistant chemist at the station, has resigned and accepted a position as consulting chemist with a firm of chemical fertilizer importers in New York City.

RHODE ISLAND COLLEGE.—College Hall, the main building of the Rhode Island Agricultural and Mechanical College, occupied as a dormitory and recitation rooms, was destroyed by fire January 27, 1895. The building was of stone, four and a half stories high, and cost about $45,000. A portion of the apparatus was saved, but much of the students' furniture and personal effects was lost. The State carried no insurance on the property. Temporary accommodations have been put up. It is proposed to erect a dormitory without recitation rooms on the site of the old building, and a drill hall 130 by 40 ft., the lower story of which will be devoted to chapel and recitation rooms, and the basement to carpenter shop for the mechanical department, bath rooms, etc.

IMPERIAL INTERNATIONAL EXHIBIT OF AGRICULTURAL MACHINES AT VIENNA.—The Imperial Agricultural Society of Vienna, under the patronage of His Imperial Highness the Archduke Carl Ludwig, will hold in Vienna on May 4, 5, 6, and 7, 1895, an international exhibition of agricultural machinery. The exhibition will be divided into the following departments: Agriculture and agricultural industries; forestry and forest industries; fruit and viticulture; animal industry; dairying; fish culture; veterinary work and horseshoeing; electricity as applied to agriculture and forestry; and an annex for seeds and artificial manures.

PERSONAL MENTION.—H. Molisch has been chosen professor of vegetable anatomy and physiology, and director of the institute of vegetable physiology of the University of Prague.

EXPERIMENT STATION RECORD.

VOL. VI. No. 8.

The act of Congress making appropriations for the United States Department of Agriculture for the fiscal year ending June 30, 1896, carries the following general items: For the Office of the Secretary of Agriculture, $94,140; Weather Bureau, $885,610; Bureau of Animal Industry, $812,000, including $12,000 for quarantine stations; Office of Experiment Stations, $30,000 ($15,000 is also appropriated for the continuance of the investigations on the nutritive value of human foods which are carried on through this office largely in coöperation with the agricultural colleges and experiment stations); Division of Statistics, $145,160, of which $10,000 may be expended in continuing the investigations concerning the feasibility of extending the demands of foreign markets for the agricultural products of the United States; Division of Entomology, $29,500; Division of Chemistry, $32,000, of which $5,000 is for the continuance of investigations of the adulterations of foods, drugs, and liquors, and $5,000 for the continuance of the investigations relative to the various typical soils of the United States, to determine their chemical characteristics, and especially the nature of the nitrifying organisms contained therein ($10,000 is also appropriated to continue experiments in the manufacture of sugar); Division of Botany, $33,800; Division of Forestry, $33,520; Division of Ornithology and Mammalogy, $27,560; Division of Pomology, $12,500; Division of Vegetable Physiology and Pathology, $26,500; Division of Microscopy, $7,300; Division of Agricultural Soils, $15,000; Division of Agrostology, $15,000; Division of Seeds, $199,120, of which $50,000 may be expended for the preparation, printing, and publishing of farmers' bulletins, two-thirds of which shall be supplied to Senators, Representatives, and Delegates in Congress for distribution among their constituents as seeds are distributed; Division of Publications, $8,300; for illustrations and engravings, $15,000; Document and Folding Room, $9,040; Division of Accounts and Disbursements, $17,300; library, $6,000; museum, $5,400; experimental gardens and grounds, $32,000; irrigation investigations, $15,000; inquiries relating to public roads, $10,000; furniture, repairs, postage, and contingent expenses, $37,000; total, $2,578,750. The act also contains an appropriation of $720,000 for the agricultural experiment stations established under the act of Congress of March 2, 1887.

It will be observed that under this appropriation act a new division will be established in the Department, namely, the Division of Agrostology, which will conduct field and laboratory investigations relating to the natural history, geographical distribution, and uses of the various grasses and forage plants and their adaptability to special soils and climates; and that the Division of Agricultural Soils, which has hitherto been connected with the Weather Bureau, will be an independent division. The Division of Records and Editing has added to its other duties the general charge of illustrations and the publication and distribution of farmers' bulletins. It will hereafter be designated as the Division of Publications.

The provisions of the act of Congress of March 3, 1891, relative to meat inspection have been amended so as to read as follows:

"SEC. 2. That the Secretary of Agriculture shall also cause to be made a careful inspection of all live cattle the meat of which—fresh, salted, canned, corned, packed, cured, or otherwise prepared—is intended for exportation to any foreign country, at such times and places, and in such manner as he may think proper, with a view to ascertain whether said cattle are free from disease, and their meat sound and wholesome, and may appoint inspectors who shall be authorized to give an official certificate clearly stating the condition in which such cattle and meat are found, and no clearance shall be given to any vessel having on board any fresh, salted, canned, corned, or packed beef being the meat of cattle killed after the passage of this act for exportation to and sale in a foreign country from any port in the United States until the owner or shipper shall obtain from an inspector appointed under the provisions of this act a certificate that said cattle were free from disease and that their meat is sound and wholesome.

"SEC. 4. That said examination shall be made in the manner provided by rules and regulations to be prescribed by the Secretary of Agriculture, and after said examination the carcasses and products of all cattle, sheep, and swine found to be free of disease and wholesome, sound, and fit for human food shall be marked, stamped, or labeled for identification, as may be provided by said rules and regulations of the Secretary of Agriculture. Any person who shall forge, counterfeit, simulate, imitate, falsely represent, or use without authority, or knowingly and wrongfully alter, deface, or destroy any of the marks, stamps, or other devices provided for in the regulations of the Secretary of Agriculture, of any such carcasses or their products, or who shall forge, counterfeit, simulate, imitate, falsely represent, or use without authority, or knowingly and wrongfully alter, deface, or destroy any certificate or stamp provided in said regulations, shall be deemed guilty of a misdemeanor, and on conviction thereof shall be punished by a fine not exceeding one thousand dollars, or imprisonment not exceeding one year, or by both said punishments, in the discretion of the court."

The Secretary of Agriculture is also authorized "to make such rules and regulations as he may decide to be necessary to prevent the transportation from one State or Territory or the District of Columbia into any other State or Territory or the District of Columbia, or to any foreign country, of the condemned carcasses or parts of carcasses of cattle, sheep, and swine which have been inspected in accordance with the provisions of this act."

AGRICULTURAL INVESTIGATION IN SWITZERLAND.

DR. A. GRETE,
Director of the Swiss Agricultural-Chemical Experiment Station of Zurich.

Agricultural investigation in Switzerland was until very recently comparatively undeveloped, if we exclude experiments conducted on private estates, which could scarcely claim to be of scientific value. The first attempts at a scientific treatment of important agricultural questions were made at the experiment station established in connection with the agricultural school of the Canton of Bern at Rüti, near the city of Bern, but for a long time this station did not do more than make analyses of various kinds, the real experimental feature being allowed to fall into the background.

At this period Schatzmann, director of the Dairy Experiment Station at Lausanne, materially advanced the cause of the dairy industry by lectures, consultations, etc., at various places, and also by maintaining a depot for dairy utensils for demonstration and for sale. For a long time after the death of Schatzmann[1] there was no conspicuous advocate of the dairy industry of Switzerland, and little was done in experimental inquiry at the Rüti Station, although that station had been extended to embrace dairy investigations. In 1887, however, there was a revival of this subject when Schaffer, Bondzynski, and Freudenreich commenced the publication in *Landwirtschaftliches Jahrbuch der Schweiz* of accounts of the following investigations:

By Schaffer: Concerning casein and the effect of rennet on cows' milk (1887); Contributions to the knowledge of the effect of rennet, and of the process of ripening of cheese (1888); Udder inflammation of cattle and its importance in agriculture (1888); Concerning the effect on milk of the internal use of bitter and aromatic medicines (1888). By Bondzynski and Rufi: Concerning the method of Werner-Schmid for the determination of fat in milk (1889). By Bondzynski: Concerning the nature of butter fat (1889). By Schaffer and Bondzynski: Concerning the physical and chemical changes of milk due to milk defects and udder inflammation in cattle and goats (1890). By Freudenreich: Concerning a new bacillus found in swelled cheese (1890).

At various times, and especially in the year 1882, steps were taken by the Swiss Agricultural Society to induce the general government to establish a federal dairy station for theoretical and practical work, but the carrying out of this plan has been deferred from time to time. Later an attempt was again made to combine with the agricultural experiment station an animal industry station with the addition of the necessary land, principally for the carrying out of feeding experiments, and to establish an Alpine agricultural experiment station. The last projects are still far from realization, but a division for dairy investigations established in connection with the Agricultural Institute at Lausanne (Dr. S. Bieler, director) in 1889 has made notable progress.

---

[1] The more important of Schatzmann's articles were published in the *Alpwirtschaftliche Monats-blätter*.

By the decree of August 23, 1888, a dairy experiment station was established at the Lausanne Agricultural Institute in connection with the existing Wine Experiment Station (Dr. J. Dufour, director), and in September, 1888, an order issued by the Council of State of the Canton of Vaud provided that this station should consist of (1) a bureau for information, investigation, and technical expert opinion in the dairy industry; (2) a collection of apparatus and necessary utensils for dairying; (3) a chemical laboratory for investigations and experiments in dairying; and (4) a laboratory for experiments in the technology of dairying. Provision was made for an expert to direct the technical work in dairying, at a salary of from $600 to $1,000 per year; a chemist, at $600 to $1,000; a chemist's assistant, at $300 to $400; and a laboratory assistant, at $120 to $200.

This order further provided that the appliances of the station and its experiments and collections should be utilized for the purpose of agricultural instruction; and that practical cheese schools should be established in the cantons after consultation with the community or the society of cheese manufacturers.

The Department of Commerce and Agriculture was charged with the enforcement of this order, and with general supervision of the station, although the Council of State is responsible for its personnel.

The position of director was filled in April, 1889, and in November, 1889, the Dairy Experiment Station (Dr. G. Martinet, director) in connection with the Agricultural Institute of Lausanne was opened. Later an agricultural station (Dr. E. Chuard, director) was added to it.

The official journal for the Dairy Experiment Station was *Chronique Agricole et Viticole*, a monthly publication dating from the latter part of 1888. In 1891, however, there was added to this station a forestry experiment station, coöperating with the forestry experiment station at Zurich, and the name of the official organ was changed to *Chronique Agricole du Canton de Vaud.*

As regards viticulture, west Switzerland has had for a long time a school of instruction in the Viticultural Station of Lausanne, but not until 1891 did east Switzerland obtain such in the Experiment Station and School for Fruit, Wine, and Garden Culture, in Wädensweil, on the Lake of Zurich, conducted by Prof. Dr. Müller-Thurgau, both of these being cantonal institutions. During its short existence this experiment station has already done good service for native fruit and vine culture, especially in regard to vine and fruit tree management, and wine and must improvement. The reports of the station appear in the *Sweizerische Zeitschrift für Obst- und Weinbau*, which, under the name of *Monatsschrift für Obst- und Weinbau*, was for twenty-five years the organ of the Swiss Fruit and Wine Culture Association.

A few years since an experiment garden for demonstration was acquired by the teachers of fruit and wine culture in the agricultural school of the Polytechnic Institute of Zurich, and the professor of agriculture has been provided with an experimental field at Strickhof, near Zurich.

The great development which the fertilizer industry has lately made in Switzerland has been accompanied by a similar expansion of official control. Prior to 1878 many domestic factories of artificial manures existed, and foreign firms shipped their product into Switzerland, but nowhere was there any control of their production, or, at least, only so far as individuals saw fit to have tests made at their own expense. It was, therefore, a step in the right direction when the so-called warehouse control was established. Under this system a chemist of the Polytechnic Institute undertook a partial inspection of fertilizers in the factories whose proprietors would consent to the investigation, and these results were made public. It is evident, however, that such a control offered no security to the purchaser, for the product found in the warehouse could be subjected to many changes before being sold to the farmer.

It was, therefore, a decided advance when in 1878 a federal agricultural control station for fertilizers and feeding stuffs, and a seed control station under separate direction, were established by the government, and authorized to arrange with the interested firms a system of control by which the farmer obtained the advantage of a free examination of the purchased goods. To these federal stations two cantonal stations have been added, an experiment farm at the Agricultural Institute at Lausanne, and a station at Rüti near Bern, coöperating with the Chemical Experiment Station of Bern (Prof. Dr. Rossel, director). The latter had been organized the previous year and is confined to the Canton of Bern and the surrounding country, while the federal institution extends its work over all the cantons of Switzerland, including Bern. Recently the work of the station has been extended to include especially culture tests of soils, and for this purpose an experiment garden with greenhouses adapted to pot culture has been provided.

The Federal Seed Control Station and the Agricultural Experiment Station of Zurich were established by a resolution of the federal council of March 17, 1877, at the federal Polytechnic Institute at Zurich. They were placed under the supervision of the Swiss school council, which, since 1885, has exercised its control through a supervisory commission. The management of each of these stations is intrusted to a director chosen by the federal council, who, with his assistants, transacts the current business.

THE FEDERAL SEED CONTROL STATION.

The extraordinary encouragement this station received from the farmers and the dealers of Switzerland and foreign countries caused a rapid growth of the institution and made enlargement of accommodations and working force necessary. At present there are in the station the director (Dr. G. Stebler), 1 male assistant, 6 female assistants, and 1 clerk. The seed control station is now located in the chemical building of the Polytechnic Institute and is well supplied with all apparatus and other material necessary. It possesses besides a greenhouse for the carrying on of germination experiments, a small experiment field near by for culture tests, and two more distant experiment fields, one near Pfäffikon, for the culture of litter plants, and the other on the Fürstenalp at Graubünden, for Alpine culture.

The following table shows the work of the years 1879–'93:

Work of Swiss Seed Control Station.

Years.	Firms under contract.	Number of packages.	Control tests.
1879	31	1,056	867
1880	36	1,343	903
1881	46	1,465	400
1882	53	1,792	390
1883	53	1,809	625
1884	55	1,883	432
1885	50	1,877	458
1886	56	2,247	655
1887	60	2,74[illegible]	759
1888	58	3,150	(?)
1889	67	4,009	1,176
1890	64	4,611	1,823
1891	72	4,849	1,486
1892	73	5,579	1,365

The annual reports of the seed control station appear in *Schweizerische landwirtschaftliche Zeitschrift.*

The scientific work of the station is directed principally to the investigation of forage plants and to culture tests on the experiment fields.

The following articles, for the most part jointly prepared by Dr. Stebler and Prof. Dr. Schröter, have appeared in *Landwirtschaftliches Jahrbuch der Schweiz:*

Contributions to the knowledge of meadows and pastures of Switzerland: Method and object of the investigation of meadows and pastures of Switzerland (1887); Investigation concerning the influence of manure on the structure of the stigmas of meadow grasses (1887); Concerning the influence of irrigation on the structure of the stigmas of meadow grasses (1887); Influence of grazing on the structure of turf (1887); A heavy yielding form of French rye grass (1888); Influence of the size of the seed kernel on the yield of green fodder by white horse tooth corn (1888); Borst grass (*Nardus stricta*), a bad enemy of our Alpine agriculture (1888); and The Fürstenalps and the culture of forage plants on the Alpine experiment field of the same (1889).

THE SWISS AGRICULTURAL-CHEMICAL EXPERIMENT STATION OF ZURICH.

In the early history of this station the director gave the closest attention to the development of the control relation between the station and the merchants, and also to increasing the efficiency of the control. It was obvious that a thorough inspection of all the fertilizers and feeding stuffs which came on the market could not be obtained by pressure from the station, so the attempt was made to induce the business houses to voluntarily submit all their goods to inspection by the station, under a contract by which the purchasers could afterwards have the goods examined by the station free of cost, and which bound the firms to pay indemnity to the purchaser should the wares prove to be below the guaranteed grade.

On the basis of such a contract the purchasers are offered fertilizers and feeding stuffs of guaranteed composition, with a free control analysis, provided they fulfill certain formalities as to drawing the sample, packing the same, witnesses, etc. In case the goods fall below the guaranty, the contracting firms, so-called "control firms," agree to pay the purchaser an indemnity depending upon the extent of the shortage. If the shortage is within certain limits, given below, the indemnity is only partial and is fixed by a prescribed tariff; but if the shortage exceeds these limits the indemnity covers the total value of the shortage. The limits are as follows:

	Per cent.
In fertilizers:	
For phosphoric acid and potash	0.5
For nitrogen in fertilizers containing 5 per cent or more	0.5
For nitrogen in fertilizers containing less than 5 per cent	0.3
In feeding stuffs:	
For protein	2.5
For fat	0.5

The value of the excess of one constituent may, to a certain degree, be used as an offset to the indemnity required for shortage of another, provided the above limits are not exceeded; otherwise indemnity may be demanded to the full value of the shortage.

For the convenience of the purchaser a certificate is given by the factory, which, after being filled out by the purchaser and the witnesses of the sampling, entitles him to a subsequent examination of the sample free of charge. Nevertheless, the purchaser can without special permission from the factory, by right of one of the regulations, have an examination of the goods made by forwarding to the station the invoice with certificate of witnesses of the sampling.

The station also twice a year makes known to the farmers the price list of all the "control" firms, warning them that the fertilizers and feeding stuffs of these firms only will be given free control analyses by the station. The results of the examinations are officially reported to those sending samples.

The equipment of the station.—The station was originally installed in a small room of the agricultural school, but it has gradually spread itself into a large number of workrooms. Hand in hand with this expansion, there has been a steady increase of the working force until, at the present time, the personnel of the station consists of a director (Dr. A. Grete), 5 permanent assistants, 2 clerks, 1 helper, and 1 botanical assistant, besides 5 temporary assistants employed during the spring.

For such extended work the old apartments in the agricultural school of the Polytechnic Institute were not sufficient, and consequently in 1886 new quarters were secured in the new federal chemical building. The experiment station was assigned the entire first floor, about 98 feet long and 33 feet wide, and the larger part of the basement.

The first floor contains the director's office, to which is attached his private laboratory; a dark room for spectroscopic and similar work; a large room for collections, and a smaller one used for storage of the delicate apparatus, and also, since 1890, for the microscopic examination of the feeding stuffs, under the charge of a special botanical assistant; and various laboratories so arranged that each investigation which the station is most frequently called upon to make may have its special department, devoted to its special purpose and equipped according to the needs of the case. This arrangement relieves the other laboratories of all determinations not directly bearing on the investigations to which they are devoted. One laboratory is devoted almost exclusively to the determinations of water-soluble phosphoric acid, the solutions being made in the cellar and sent direct to the chemist, for analysis, by means of an elevator. This laboratory has lately been provided with a large revolving titration machine, which is arranged to simultaneously titrate 10 samples with molybdic acid solution, as described by the author in *Berichte der deutschen chemischen Gesellschaft.*

There is also a large and well-equipped general laboratory in which chiefly determinations of phosphoric acid insoluble in water are made. This laboratory is furnished with 3 double worktables, standing in the middle of the room, and 4 hoods. Each assistant is thus provided with a hood, under which is arranged a sand and water bath. This laboratory is also provided with a blast, driven by a water motor, and has distilled water on tap at two points.

A similarly equipped laboratory is set apart for potash determinations, although it is often utilized for some other purposes. The atmosphere of this room is kept ammonia-free. A room opens off this large laboratory which is furnished principally with the apparatus required for nitrogen determinations. In hoods are the necessary furnaces, ovens, etc. On a large table in the middle of the room are arranged distilling apparatus[1] and condensers, and racks with standard solutions for titrating.

---

[1] As distillation flasks, the so called Erlenmeyer flasks of tinned copper, first suggested by the author, have been used for a long time with excellent results.

Adjoining these 3 laboratories is the weighing room, which has space for 12 balances. Here, also, is a small library of reference books needed in ordinary laboratory work.

The washing of apparatus is done in a special wash room.

In a room adjoining the general laboratory the purely clerical work is done. The assistants prepare detailed reports of results on small sheets at their worktables, fasten these sheets together, and hand them into the record room, where they are entered in special books bearing the numbers of the assistants.

The basement space allotted to the station is devoted principally to appliances for drying and preparing samples for analysis, force pumps, distillation apparatus, storage, and a technological laboratory.

Coarse fodders are prepared for analysis by being passed through a cutting machine, and after thorough drying finely ground by a Grüson Excelsior mill. Granular, dry, not too hard materials are immediately put through the same machine. The finest powder is prepared by the Dreefs mill. With superphosphates these machines can not be used, as their iron parts are attacked by the acid, and the final results might be affected. For these materials a mill in which the fertilizer comes in contact only with porcelain has been devised, which has given excellent results. These mills are all operated by a water motor.

The still used was made from special designs by the author, and is arranged not only to distill liquids directly or with steam, but to rectify them at the same time. The same apparatus is also arranged to accommodate evaporating dishes of different sizes, and may be connected with a vacuum, without, in most cases, interfering with the distillation of water or other solutions.

All the apartments are provided with complete electrical service.

The work of the institution.—Convinced of the security afforded by the above described control of fertilizers and feeding stuffs, the farmers have year by year more fully availed themselves of the privilege of having the guaranties accompanying purchased goods confirmed by the station analysis, so that at present in many localities no one thinks of using fertilizers on a large scale without taking advantage of such examinations. For this reason the number of analyses each year is very large.

In the year 1878 only 47 samples were received for examination. The numbers received during succeeding years were as follows:

Summary of station work.

Years.	Investigations.	Quantitative determinations.	Free control analyses.
1879	180	640	57
1880	254	920	94
1881	604	2,090	316
1882	690	2,800	438
1883	642	2,762	389
1884	803	4,419	457
1885	900	5,005	652
1886	1,140	6,250	926
1887	1,260	6,881	980
1888	1,323	7,604	1,077
1889	1,595	9,108	1,237
1890	1,867	10,012	1,333
1891	2,296	12,727	1,678

The number of "control firms" who gave the farmers the right to free analysis was as follows:

Number of control firms.

Years.	Fertilizer firms.	Feeding stuff firms.	Total.
1878	5	0	5
1879	10	3	13
1880	12	4	16
1881	17	6	23
1882	19	5	24
1883	20	7	27
1884	20	7	27
1885	24	10	34
1886	22	6	28
1887	22	6	28
1888	20	5	25
1889	20	5	25
1890	23	5	28
1891	23	6	29

Besides this annual routine analytical work the station has carried out a series of scientific practical investigations, among which are the following reported by Dr. Grete in articles published for the most part in *Landwirtschaftliches Jahrbuch der Schweiz*, 1887–'88: Experiments concerning the proper time to cut hay; Investigations of the composition of Swiss litter plants; Investigations concerning liquid manure; Experiments concerning the preservation of green food by means of carbon bisulphid; Concerning the extract in wine;[1] Determination of phosphoric acid by titrating with molybdic acid;[2] Report on the results of fertilizer experiments conducted in Switzerland in 1885 and 1886; and Investigations of the Swiss barks used for tanning.[3]

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

A digestion flask for obtaining the acid solution in soil analysis, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 248–251, figs. 2*).—Digestion in porcelain beakers as proposed by Hilgard is open to the objection that the acid partly evaporates and consequently varies somewhat in strength, and in using the stoppered bottles recommended by Kedzie "it is difficult to obtain bottles that will stand so high a pressure for so long a time, and it requires a very perfect-fitting stopper to prevent any interchange between the hot solutions in the water bath and the acid in the bottles."

"The flask [proposed by the author] has a capacity of 100 cc. The ground-glass stopper is provided with an exit tube that can be connected with a small glass tube or a condenser. . . .

"A compact form of condenser can be made from a galvanized iron pail by perforating the bottom with holes a little larger than the glass tubes that are to be inserted, and making the joints water-tight by means of rubber tubing. Long glass tubes can be used without any condensing apparatus. A cover is also provided for the water bath with small openings to allow the condensing tubes to pass through.

"The soil is weighed direct into these digestion flasks, and the proper amount of acid added. The flasks are then placed in the water bath and connected with the condensers. At the end of the fourth day the solution and insoluble residue is transferred to a casserole, and all of the remaining determinations are made in the usual way."

The results of comparisons of the three methods on soils of different character are reported.

"Under the same conditions the digestion flasks and the glass-stoppered bottles give practically the same results, with the advantage as to rapidity and less liability of losses in favor of the digestion flasks. Both of the methods give higher results for the potash and the alumina than the covered beaker. This is due to the action of the acid upon the soils at a more uniform temperature and maintaining the acid at its initial strength."

A new gasometric method for determining nitrogen in nitrates, F. GANTTER (*Ztschr. analyt. Chem., 34 (1895), No. 1, pp. 25–32, fig. 1*).—The method is based upon the facts that (1) nitrates are reduced to nitrites when heated in concentrated solution with phosphorous and sulphuric acids, and (2) when nitrite solutions are heated with ammonium chlorid the nitrogen of both the nitrite and the ammonium chlorid is set free, as shown by the following equations:

$$N_2O_5+P_2O_3=N_2O_3+P_2O_5.$$
$$N_2O_3+2NH_4Cl=2N_2+3H_2O+2HCl.$$

The method is conducted as follows: Three cubic centimeters of a solution which should contain not more than 300 mg. of nitrate with 500 mg. each of crystallized ammonium chlorid and crystallized phosphorous acid are placed in the digestion flask of a special form of gas generator which is described, and 2 cc. of sulphuric acid (2 parts of concentrated sulphuric acid and 1 of water) is added. The digestion flask is provided with a pipette in its mouth, in which 5 cc. of sulphuric acid (2 to 1) is placed, and is also connected with an absorption apparatus containing soda solution for purifying the nitrogen generated. This apparatus is placed in a cooling cylinder and the generating flask very slowly and carefully heated with the smallest possible flame. This soon produces a slow and uniform evolution of gas, which gradually increases, so that after a time the flame must be removed in order to check the too rapid generation of gas. The latter should be so regulated that the solution is not colored yellow, and when it has almost ceased the sulphuric acid in the pipette is allowed to run into the flask, which is warmed again and the solution gradually raised to the boiling point. This is continued until no further evolution of gas takes place, when the solution is strongly heated for a few minutes. This heating, however, must not be continued so long that the solution in the flask becomes colored by the concentration of the sulphuric acid. The nitrogen evolved is collected in a eudiometer over water and measured.

Accurate results were obtained by this method or modifications of it on nitrate of soda, nitrate of ammonia, nitrate of potash, nitrite of soda, and drinking water.

In applying the method to the examination of nitrate of soda 300 mg. each of phosphorous acid and ammonium chlorid instead of 500 mg. is used.

The method can be employed in the determination of very small amounts of nitric acid, and hence is applicable to the examination of drinking water. In this case the residue from the evaporation of 500 cc. of water is taken up in a little water and filtered into the digestion flask, in which the filtrate is evaporated nearly to dryness. To the residue 2 cc. of dilute sulphuric acid (2 to 1) and 100 mg. each of ammonium chlorid and phosphorous acid are added, and the operation conducted as above described.

On a new volumetric method for determining phosphoric acid in pure solutions, R. SEGALLE (*Ztschr. analyt. Chem., 34 (1895), No. 1, pp. 33–39*).—Various methods proposed for this purpose are briefly reviewed, and determinations by gravimetric analysis, volumetric analysis (using phenolphthalein as an indicator), by R. Maly's method[1] (original and modified), and by C. Glücksmann's method (as modified by J. Langer[2]) are reported.

The results are favorable to the Glücksmann method as compared with the others tested, and this method is recommended for adoption as a standard volumetric method, being especially valuable for pharmaceutical chemists.

Argon, a new constituent of the atmosphere, Lord RAYLEIGH and W. RAMSEY (*Chem. News, 71 (1895), No. 1836, pp. 51–63*).

The synthesis of albuminoid compounds, LILIENFELD (*Rev. Scientif., 1895, No. 3, p. 87*).—A notice of an article read before the Biological Society of Berlin.

A study of the vegetable alkaloids, E. ARMENDARIS (*Mem. Rev. Soc. Cient. "Antonio Alzate," 8 (1894–'95), No. 1 and 2, pp. 11–29*).—The method employed and the results obtained in a detailed study of these compounds are reported.

On the chemistry of chlorophylls, E. SCHUNCK and L. MARCHLEWSKI (*Liebig's Ann. Phys. und Chem., 284, No. 1 and 2, pp. 81–107*).—A second paper, the first being published in the same journal, vol. 278, p. 329.

On the determination of iron oxid and alumina in mineral phosphates, W. HESS (*Ztschr. angew. Chem., 1894, No. 22, pp. 679–683*).

On a new method of determining fat in milk, P. FERNANDEZ-KRUG and W. HAMPE (*Ztschr. angew. Chem., 1894, No. 22, pp. 683–687*).

Improved laboratory apparatus, J. VOLHARD (*Liebig's Ann. Phys. und Chem., 284, No. 1 and 2, pp. 233–244, figs. 5*).—The apparatus described include a water bath with constant level, oven for heating sealed tubes, and a gas furnace for elementary analysis.

Volumetric and colorimetric analysis, W. H. SYMONS (*Pharm. Jour. and Trans., 54 (1895), No. 1284, pp. 652–655, fig. 1*).

The scientific principles of analytical chemistry, W. OSTWALD (*Die wissenschaftlichen Grundlager der analytischen Chemie. Leipzig: W. Engelman, 1894*).—Reviewed in *Phil. Mag. and Jour. Sci., 39 (1895), No. 237, p. 225*.

Notes on the Grandeau method for humus, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 251–254*).—This is a reprint of an article first published in *Jour. Amer. Chem. Soc., 16 (1894), No. 3, pp. 210–213* (E. S. R., 5, p. 932).

Methods of determining sugar and starch, J. M. BARTLETT (*Maine Sta. Rpt. 1893, p. 37*).—A detailed description is given of the individual methods with acid and with diastase.

Agricultural chemical contributions, V. STEIN (*Tidsskr. Landökon, 12 (1894), pp. 857–867; 13 (1894), pp. 722–737*).—A summary of agricultural-chemical work performed for the Royal Danish Agricultural Society during 1894.

BOTANY.

Grasses of Tennessee, II, F. LAMSON-SCRIBNER (*Tennessee Sta. Bul., vol. VII, No. 1, pp. 141, figs. 187*).—Part I of the Grasses of Tennessee,[3] when issued, was intended as preliminary to the part here presented, but considerations led to a modification of this plan and the present bulletin is complete in itself, and, as the author says, "may be called a handbook of the grasses of Tennessee." Descriptions of all the genera and species known to occur within the State are given, and under the specific descriptions are added economic notes whenever they would be of value or interest. In the descriptions of the tribes and genera notes are given on their numerical abundance and geographical distribution throughout the world, from which their relative representation in the region covered by the bulletin may readily be seen. There are more than 200 species and varieties of introduced and indigenous grasses described, representing 65 genera of 11 tribes, and most of them are figured, some for the first time. The illustrations, which were especially prepared for this work, show the general habit of the plant, the inflorescence and dissections of the spikelets, the latter being drawn to a larger scale than those showing the entire plant. For nearly every genus of more than a single species an analytical key of species is given that will materially aid in the determination of specimens. A feature of the bulletin is the index and glossary in which every scientific name and technical term used is concisely defined, in addition to the usual references to figures and pages. The most widely known common name of each species is given, and the scientific nomenclature is not burdened with a list of synonyms that are valuable only to a specialist. The nomenclature followed is in the main that used in the manuals covering the same region. The bulletin, while containing only the grasses of Tennessee, will be valuable to most of the eastern and central part of the United States, the region covered by Gray's Manual, the edition of 1890 of that work containing less than a score of genera not included in this bulletin.

Notes on maize, E. L. STURTEVANT (*Torrey Bul., 21 (1894), No. 12, pp. 503–523*).

Synopsis.—Notes are given on crossing of species, crossing of varieties, mummy corn, effect of climate on the growth, growing season required for corn, and the physiology of pop corn.

The author thinks from the data given that it is highly probable that cross-fertilization is very common, at least within each species, but that there is some resistance to hybridization; however, more data are required before claiming the demonstration of the generalization. Within varieties color variation is very common. Descriptions are given of 4 varieties of mummy corn, 3 of which are from Peru, the other from Chile. All belong to the species *Zea amylacea.* The author offers a few generalizations on the effect of climate on corn. He says the common belief that a northern climate increases earliness and decreases size is not borne out by his observations, and the idea that we must go North for seed is untenable except that in the North are found only varieties maturing within certain periods. He thinks earlier corn must be sought by finding earlier varieties, whether in the North or South. The author gives as an explanation of the phenomenon of corn popping the fact that hot water causes starch to become plastic. In the pop corn the starch lies within a very tough endosperm and the application of heat causes the starch to swell; the liberated steam bursting the grain, exposes the white fluffy mass of swollen starch. In the case of the nonpopping corns, the endosperm is too thin and only splits to liberate the steam. Aboriginal names are given for parched or variously prepared kinds of corn.

Pentosans in plants, G. DE CHALMOT (*Amer. Chem. Jour., 16 (1894), pp. 589–611*).—The author found from 80 to 90 per cent of furfurol-yielding compounds in barley sprouts germinating in darkness, and separated from them a pentosan which yielded pentose on inversion. His investigations indicated that these furfurol-yielding bodies belong to the nitrogen-free extract, and are not derived from the cellulose, as suggested by Cross and Bevan. It is claimed that the fact that cane sugar interferes with the phloroglucol reaction explains the failure of these investigators to find pentosans in barley sprouts grown in darkness.

The author found that the amount of pentosans increased in germinating corn with the advance of germination. The amount in peas first increased, then decreased. Both in corn and in peas the amount in the seeds proper decreased, and that in the stems and roots steadily increased during germination. The increase of pentosans in the stems and roots of peas (and clover) is, however, not nearly so pronounced as that in the stems and roots of corn.

The author holds that the pentosans in the roots and stems are not derived from the seeds, but are formed from other plant constituents.

The amount of pentosans in the germs is but slightly affected by the presence or absence of light during germination.

In connection with the discussion of this topic a table is given showing percentages of pentosans found in seeds by the author and others.

Extensive experiments showed that nitrates supplied to the germinating corn increased the amount of pentosans dissolved from the seed. At the same time the stems and roots were poorer in pentosans but richer in albuminoids, the influence of the nitrates in this respect being very pronounced.

It was also observed that the pentosans of pine wood increased during growth, a fact which is in accordance with results obtained with all other growing parts of plants.

The evidence supporting the author's hypothesis that pentosans are not the result of the processes of assimilation but are formed from hexoses is discussed in detail.

Influence of drying on the respiration of tubers, J. F. LUND (*Rev. gén. Bot., 6 (1894), No. 69, pp. 353–355*).—The author has investigated the tubers and fleshy roots of artichoke, onion, radish, potato, and carrot. It was found that specimens ripened and kept over winter decreased in their respiration with their decrease in weight due to desiccation. In the case of young tubers collected in April or May that were formed during the season there was a slight increase in their respiration following a slight loss of water.

A manual of orchidaceous plants (*Chelsea: Jas. Veitch & Sons, 2 vols., pts. 10*).

Notes on Antigua grasses, C. A. BARBER (*Suppl. Leeward Islands Gaz., 1894, No. 32, pp. 165–170*).—Popular notes are given on Guinea grass (*Panicum jumentorum*), *Andropogon caricosus*, Bermuda grass, *Andropogon saccharoides*, and *Sporobolus indicus*.

The philosophy of flower seasons and the phenological relations of the entomophilous flora and the anthophilous insect fauna, C. ROBERTSON (*Amer. Nat., 29 (1895), pp. 97–117, pls. 3*).

Sensitive movements of some flowering plants under colored screens, J. M. MACFARLANE (*Bot. Centbl., 61 (1895), No. 4, pp. 136–146; No. 5, pp. 177–184*).

Concerning heliotropism, W. ROTHERT (*Cohn's Beiträge Biol. Pflanzen, 7 (1894), No. 1; abs. in Bot. Ztg., 53 (1895), II, No. 2, pp. 17–25; also Bot. Centbl., 61 (1895), No. 4, pp. 159–166*).

The discussion concerning the function of the root tips, W. ROTHERT (*Flora, 79 (1894), pp. 179–218; abs. in Bot. Centbl., 61 (1895), No. 5, pp. 199–200*).—A critical review of the literature relating to the subject.

The thorns of plants, H. COUPIN (*Pop. Sci. Monthly, 46 (1895), No. 4, pp. 498–501*).

The continuity of protoplasm in plants, R. BEER (*Nat. Sci., 6 (1895), No. 36, pp. 108–111*).—A review of the theory of continuity of protoplasm and a short bibliography of some of the more important contributions to the subject.

Mold and other growths found in the seed cavities of apples, L. MOORES (*Amer. Micr. Jour., 16 (1895), No. 2, pp. 49–54, figs. 2*).—The author reports the common growth found in seed cavities to be internal hairs. A *Penicillium* sometimes gains access through large openings at pip end or more commonly through insect burrows.

The coloring of apples (*Gard. Chron., 17 (1895), ser. 3, pp. 177, 178*).—A controversial article on the relative importance of direct sunlight and soil constituents on the production of high colors.

FERMENTATION—BACTERIOLOGY.

The microörganisms of fermentation, A. JOERGENSEN, translated by P. FREUND (*Les Microrganismes de la fermentation. Paris: 1895, pp. 318, figs. 56*).—Reviewed in *Rev. Scientif., 10 (1895), No. 3, p. 83*.

Recent researches on pectase and pectic fermentation, G. BERTRAND and A. MALLÈVRE (*Compt. Rend., 120 (1895), No. 2, pp. 110–112*).

The bacteria of drinking water, especially of the Chemnitz water supply, O. E. R. ZIMMERMANN (*Zwölfter Ber. Naturw. Ges. Chemnitz, pp. 79–168, pls. 5*).

A simple apparatus for disinfecting with steam, L. VAILLARD and BESSON (*Ann. Inst. Pasteur, 8 (1894), No. 12, pp. 833–853, figs. 5*).

ZOÖLOGY.

Are all birds of prey injurious to the farmer? E. A. SMYTH, Jr. (*Virginia Sta. Bul. 38, pp. 23-39*).—This bulletin consists of notes on the feeding habits of the common hawks and owls of Virginia, with the results of the examination of numerous stomachs of each species. Much of the matter is compiled from "Hawks and Owls of the United States."[1] The following species are treated of, brief descriptions and notes on the habits being included: Marsh hawk, sharp-shinned hawk, Cooper's hawk, goshawk, red-tailed hawk, red-shouldered hawk, broad-winged hawk, rough-legged hawk, golden eagle, bald eagle, duck hawk, pigeon hawk, sparrow hawk, fishhawk, barn owl, long-eared owl, short-eared owl, barred owl, screech owl, and great horned owl. The positive economic benefit of many of these species is urged.

---

[1] U. S. Dept. Agr., Division of Ornithology and Mammalogy Bul. 3 (E. S. R., 4, p. 852).

Two tables are appended, one giving a résumé of the lists of stomach contents for each species, and the other giving the percentages of poultry or game, mice, and insects found in the food.

The weasels, B. H. WARREN (*Pennsylvania Sta. Rpt. 1893, pp. 159–168, pls. 2*).—Descriptive notes on *Putorius erminea* and *P. vulgaris*, with notes on their habits. The change of color from brown in summer to white in winter is described at some length, and colored illustrations of each pelage are given. Their food is remarked upon, and their destructiveness to poultry and game especially noted. A table is included giving the condensed reports of 100 observers in regard to the food and habits of weasels.

The destruction of animals injurious to agriculture, J. DANYSZ (*Ann. Sci. Agron., 10 (1893), I, No. 3, pp. 410–491*).—A review of work on the destruction of rodents and insects by means of contagious diseases.

METEOROLOGY.

Winds injurious to vegetation and crops, G. E. CURTIS (*U. S. Dept. Agr., Weather Bureau Bul. 11, pt. 2, Rpt. Internat. Meteorolog. Congress, 1893, pt. 2, pp. 435–444*).—Destructive winds are placed in one of the following classes: (1) Violent winds; (2) cold winds; (3) hot desiccating winds.

In the United States the tornado, the derecho, and the West Indian hurricane are the most violent of the class of winds which destroy by their force alone, but as they occur only over limited areas, or at very long intervals, their aggregate damage to fruits and crops is much less than is caused by the winds which frequently accompany local thunderstorms, and by the severe gales which often prevail during the passage of intense general storms.

The region of greatest destruction by violent winds in the United States is the Great Plains region, from Illinois westward to the boundary of cultivation. The greatest destruction is effected when such winds prevail at a late stage of the ripening grain, when the heads are thrashed out by the beating winds.

There are two classes of injurious cold winds: (1) Mountain and valley winds; (2) anticyclonic winds, or northerly winds associated with and following cyclones. In the United States mountain and valley winds do not occur to any marked extent, but in part of Europe these winds are exceedingly injurious to the vine and other tender fruits. The second class of cold winds includes those called blizzards and northers in the United States, and the mistral and bora of southern Europe. The fruit orchard is the principal victim of these piercing blasts. These cold winds are the principal enemy of the tender peach and determine the limit of its successful cultivation. A remarkable example of their effect is to be found in the climatic history of Michigan, where a half century ago peach trees flourished and were rarely injured by the cold; but after the lumberman began his work of deforestation Dakota blizzards made greater and greater inroads into the State, the tender peach trees were killed along their path, and now the peach crop has nearly disappeared. From the same cause the attempt to grow peaches in northern Kansas has been largely abandoned.

The third class of winds injurious to agriculture are those characterized by intense heat and dryness.

The hot winds of the Plains occur over a vast agricultural area and in some seasons do incalculable damage to all crops, and especially to wheat and corn, which cover the greatest acreage. The area over which they prevail extends from Dakota to Texas; in occasional seasons they occur east of the ninety-fifth meridian, but their greatest frequency and severity is westward of that meridian to the boundaries of cultivation. An illustration of their destructiveness to agriculture may be drawn from the statistics of 10 Kansas counties in 1888, which showed a loss of 21,000,000 bu. of corn alone, due principally to hot winds.

Some of the results of an investigation of the hot winds of 1889 are here given: They are usually from the southwest, and occur most frequently in July and August. They generally continue for about three days. The typical hot wind sets in at 9 or 10 a. m. and continues until about 5 p. m. In 6 hot winds reported the temperature ranged from 100 to 109° F. The average humidity probably did not exceed 25 per cent. The force of the wind varied from a "moderate breeze" to a "strong wind;" in one case it ranged from a "high wind" to a "gale." No quantitative measures of the rate of evaporation were received, but the rate was doubtless very high.

In general hot winds do not materially affect the crops until by their evaporative effect they have drained the soil of its moisture. All circumstances that conduce to diminish evaporation are most potent factors in preserving a crop of corn or wheat through a trying period. Freedom from weeds, deep plowing, and frequent cultivation which breaks up the capillary ducts in the soil, a sandy rather than a clayey surface soil, a subsoil of hardpan which stores up the rain waters for the crops to draw upon in critical periods—these are some of the conditions which diminish the rate of evaporation and delay the beginning of the drought.

Similar in effect to the hot winds of the Plains are those of the Pacific Coast. These occur in the Sacramento and San Joaquin valleys of California and to some extent in portions of Oregon and Washington. In California these winds are northerly, and are often designated as the "desiccating north wind." The greatest injury is done when the north wind occurs in May and June, during the periods when the great

California wheat crop may receive incalculable damage. In Oregon, as in California, the hot winds are especially injurious in June. Mr. B. S. Pague, of the National and the Oregon Weather Service, states:

> "Three days of hot winds may reduce yields from 30 bu. per acre to wheat not fit even for hay. The character of the wind is abnormal dryness, varying in force from 6 to 15 miles per hour, and accompanied by temperatures of from 75 to 90° F. The dry wind continues during the night, abating some, while the temperature has its diurnal change."

The California fruit grower has been among the earliest to recognize the efficacy of timber belts as a protection against the damaging effect of wind, and around many of the citrus groves of southern California may now be seen rows of eucalyptus or other trees for wind protection.

The great western plains offer the greatest sphere for the operation of timber as wind-breaks, for this is the natural home of all the destructive winds.

Many attempts at tree planting on the western plains have met with poor success because they have been improperly conducted. The aridity of the climate requires that suitable varieties be selected and properly combined; that a sufficient mass of foliage be obtained to create favorable conditions of growth, and then that the trees should not be left to themselves, but should be as thoroughly cultivated as any crop of grain. Sufficient experience has now been attained to demonstrate that, when these conditions are observed, timber strips can be successfully grown in Kansas as far west as the one hundred and first meridian, or beyond the present boundaries of successful agriculture. The last report from the experimental station at Garden City, in western Kansas, states that the timber strips planted for wind-breaks have made a marvelous growth. These strips consist of four rows of black locusts bordering all sides of a 160-acre lot, and several rows of cottonwoods on one side of an 80-acre lot.

The protective effect of standing timber as an obstruction to the wind being recognized, it is important to know to what distance this protection is extended. The extent of the protective action of a vertical obstruction is accurately exemplified by the distance to which a snow bank extends on the leeward side of a fence. This is the width of the protected strip and we desire to know its ratio to the height of the obstruction. Mr. Barnard, of Pawnee County, Nebraska, and Judge Whiting, of Iowa, are authorities for stating that the protection amounts to 1 rod (16½ feet) on the ground to every foot in height of the protecting trees. Other writers give a somewhat less ratio for the distance of protection, but an average estimate is that a solid belt of trees creates a calm area on its leeward side which is, at the ground, from 11 to 16 times as wide as the height of the trees.

Observation also indicates that barriers and obstructions, like buildings and trees, diminished the general velocity of the surface wind beyond the limits of their immediate protective influence. These data, therefore, lead us to believe that if timber strips are planted at distances apart not greater than a half mile, or in other terms, if every 160-acre lot is surrounded by a belt of trees like that at Garden City, a very considerable protection will be afforded to the entire acreage.

If the plains of Kansas were cross-sectioned by such timber belts, platting the State into 160-acre lots, the blizzards and the hot winds that now possess an unobstructed passage would be stayed in their course, their blighting and desiccating effects would be largely diminished, and thereby a long step would be taken toward that climatic amelioration which alone is wanting to make a large part of the prairie a veritable garden spot.—O. L. FASSIG.

Variations in the character of the seasons, H. GAWTHROP (*Amer. Met. Jour., 11 (1895), No. 9, pp. 332–339*).—The author presents figures showing the course of temperature at Philadelphia from October, 1888, to October, 1893, which period he divides up into 44 courses averaging 42½ days each. As a substitute for his plan of averaging daily means in 30-day periods the courses which he now adopts are not restricted to any definite number of days; in fact, the longest of the 44 comprises 191 days, viz, from January 2, to July 12, 1890. After some very general remarks he concludes—

> "The primal cause for the variations in the character of our seasons must be traced back through all the effects of diurnal and seasonal insolation, and of the cyclonic storms in the lower atmosphere, where it is manifested to us, up to the ever-flowing westerly current above. . . .
>
> "The vast movement from west to east of the upper atmosphere in our middle latitudes, extending to a width of 2,000 miles and more, I would liken to a river with its swift current in the middle, gradually lessening in velocity at the sides and bottom, though there is one movement different from any river, and that is the oscillations north and south with the sun. . . . Like a river, however, it must have a persistence in its flow, because of the inertia of its great volume, and yet again, like a river, this inertia may be overcome, and the direction changed by obstacles or influences in its bed. A straight ditch through a meadow becomes a crooked creek, by reason of the inequalities the water meets in its flow, and the river in greater volume swings in longer stretches from bend to bend. This, then, is my thought, that the great atmospheric-river changes its course, southing at one time and northing at another, because of the influences it meets in passing over the surface of the earth."

Among the influences disturbing this upper current he enumerates the two great continents and the two great oceans of the world, the annual movement of the sun northward and southward, and the tropical cyclones. He concludes by an appeal for the exploration of the upper atmosphere.

[The exploration of the upper atmosphere is undoubtedly an important desideratum, but it may well be doubted whether there is a uniform westerly current at great altitudes doing the work that is imagined by Mr. Gawthrop.]—C. ABBE.

Rhythm in the weather, H. H. CLAYTON (*Amer. Met. Jour., 11 (1895), No. 10, pp. 376–380*).—"To most persons nothing seems more irregular and fitful than the weather. Yet I think there is good reason to believe that through all this seeming irregularity there runs a web of harmony and rhythm.

"The yearly and daily weather periods are well known, but these, I believe, are not the only regular periods to be found. A year ago I described two rhythmic periods in the weather, one of about 7¼ and the other of about 6⅙ days in length. To these I will now add two shorter periods, one of 5 days 10.8 hours, and the other of about 4 days 15 hours. The action of these on the atmosphere is usually in combination, but they independently vary in intensity, so that now one and now the other predominates and gives its especial characteristics to the weather changes."

Investigations of these periods in all parts of the world indicate unmistakably that they exist in every part both of the northern and southern hemispheres.

Observations on dates of maximum temperatures during May and June, 1894, are reported which show a close agreement of the observed dates with those indicated by the 5½ and 7¼ day periods.

"During the summer I computed a series of normal waves for each of the periods, and by taking the times of maxima and minima and the amplitude from observation, I found it possible to reproduce the observed temperature with great accuracy, and even to plot a curve for a week in advance which would represent the observed temperature or pressure very closely as long as the periods continued to run without a break. . . . The predicted and observed temperature followed almost exactly the same course; but what is most remarkable is the fact that the predicted minimum temperature and the observed minimum temperature was the lowest observed in August for more than 9 years.

"After I had made some progress in the investigation of these weather periods, an experiment was begun to ascertain how far they could be made useful in forecasting. Beginning with January 27, forecasts were published each week in a local newspaper. These forecasts consisted in stating which days were likely to be warmest and coldest, and on which rain or snow was most likely to fall. After 2 months these were verified, and it was found that of 17 days, mentioned as days on which rain was probable, rain fell on 12; while on the average for each 17 days not mentioned, rain fell on 5, indicating that the percentage of rain was twice as great on days when rain was forecasted as on other days. Two days were named each week as likely to be the warmest days. In 6 weeks out of 8 the warmest day of the week occurred on one of these. The coldest days were predicted in a similar manner, and in 4 cases out of 8 the coldest day of the week occurred on one of the days predicted. Since 2 days were included in each week, the chances were that 2 out of every 7, or 28 per cent might prove accidentally correct, while in reality 75 per cent of the warmest days were correctly predicted, and 50 per cent of the coldest.

"These facts appeared to indicate that the forecasts might prove of benefit to farmers and others, and accordingly on June 2 the issue of a weekly bulletin for general distribution was begun. These bulletins met with an encouraging support, and it was decided to continue them through the year. At the end of September, a verification of the forecasts was made, and it was found that out of 20 warm intervals predicted 13 averaged warmer than the mean of the week, and out of 19 cool intervals predicted 12 averaged cooler than the mean of the week, or about two-thirds in each case. A measurable quantity of rain fell on 33 per cent of the days on which rain was predicted, and on 20 per cent of the days on which no rain was predicted. Reports sent me from various stations indicate that this held substantially true for all of southern New England. The forecasts were made on Friday, and the success for the 5 days from Monday to Friday was about the same as for the other days.

"The excess in favor of the forecasts is not so great as I had at first hoped, but shows, as fully as it is possible to do, that the forecasts have a scientific basis, and are not merely the result of guesswork."

The difficulties which have been found to impair the accuracy of forecasting by this method are interference of the weather waves, by which one series is destroyed or its phase reversed, and two sets of storms, during October, one coming over New England from the lakes, the other from the South.

"The results were too intricate for my analysis, and produced a series of disheartening failures in the forecasts.

"Difficulties are to be expected in a new enterprise, but I am confident that they will be solved, one by one, until an exact science of the weather is constructed." The measure of success already attained is held to be "substantial evidence that the right clue to long-range weather forecasting has been found and will some day be perfected."

The moon and rainfall, H. A. HAZEN (*Amer. Met. Jour., 11 (1895), No. 10, pp. 373–375*).—Investigations made by the author at New Haven in 1880 showed "that nearly one-half more precipitation occurred at the time of new than of full moon." A study of the records for one hundred years at London yielded negative results, as did that of the rainfall of the whole country. The latter indicated "that the influence, if there were one, must be looked for in a rather circumscribed region."

The present paper records a study of the rainfall of New York City, New Haven, Connecticut, and Boston, Massachusetts, arranged according to each lunation, 296 lunations in 3 groups being represented.

"While both New York and New Haven show an increase at the time of new moon, yet the figures at Boston show a very remarkable maximum at the day of new moon, and an equally remarkable minimum on the seventeenth day of the lunation, or two days after full moon. I do not set forth these figures as an absolute proof that the moon does influence rainfall in the neighborhood of Boston, but it looks as though there must be something in it. There are at times remarkable reversals in the curves whereby a minimum point in one curve coincides with a maximum in the next, but to offset these there are remarkable coincidences; for example, a marked maximum at the twentieth day of the lunation throughout. It will require a good many more observations to prove anything one way or the other, but it would seem as though the curve at Boston could not be very materially modified with less than fifty years' observations."

Meteorological observations at Massachusetts Hatch Station, C. D. WARNER and F. L. WARREN (*Massachusetts Hatch Sta. Met. Bul. 72, pp. 5*).—Daily and monthly summaries of observations during December, 1894, and a general summary for the year. The annual summary is as follows: *Pressure* (inches).—Actual maximum, 30.47, January 17, 10 p. m.; actual minimum, 28.59, January 30, 6 a. m.; mean reduced to sea level, 30.085; annual range, 1.88. *Temperature*[1] (degrees F.).—Maximum, 97, 98, July 20; minimum, —9, —17, February 25; mean, 49.7, 47.9; annual range, 106, 115; maximum mean daily, 82.5, 84, July

---

[1] The first figures denote reading at top of tower (51 ft. above the ground), the second at base.

28; minimum mean daily, 1, —1.5, February 24; mean maximum, 57.7, 59.6; mean minimum, 38, 36.9; mean daily range, 16.5, 22.7; maximum daily range, 35, May 12, 47.5, February 17; minimum daily range, 2, 5, October 25. *Humidity.*—Mean dew point, 40.5; mean force of vapor, 0.4416; mean relative humidity, 71.9. *Precipitation.*—Total rainfall or melted snow, 32.64 in.; number of days on which 0.01 in. of rain or melted snow fell, 125; total snowfall, 71½ in. *Weather.*—Mean cloudiness observed, 50.5 per cent; total cloudiness recorded by the sun thermometer, 2,488 hours, or 54.9 per cent; number of clear days, 107; number of fair days, 83; number of cloudy days, 175. *Wind.*—Direction, SW., 17 per cent; S., 15 per cent; N., 15 per cent; NW., 13 per cent; total movement, 36,257 miles; maximum daily movement, 443 miles, April 13; minimum daily movement, 0 miles, September 29; mean daily movement, 99.4; mean hourly velocity, 4.1 miles; maximum pressure per square foot, 22½ lbs. = 67 miles per hour, February 23, 2 p. m. *Bright sunshine.*—Number of hours recorded, 2,051. *Mean ozone*, 24.9 per cent. *Dates of frost.*—Last, May 22; first, August 22. *Dates of snow.*—Last, April 12; first, November 5.

Meteorological observations at Pennsylvania Station, W. FREAR and W. S. SWEETSER (*Pennsylvania Sta. Rpt. 1893, pp. 169–173, 182–188, 193–222*).—The meteorological work of the station in 1893 was "chiefly a continuation of the work of the preceding years, including observations of the kind usually made by the United States Weather Service upon atmospheric phenomena, and also observations upon soil temperatures at various depths and upon the amount of sunshine" (E. S. R., 6, p. 115). Monthly summaries of observations and weekly crop reports are given in the body of the report and the detailed daily record in an appendix. The annual summary is as follows:

Summary of meteorological observations, 1893.

	Year 1893.	Growing season (Apr. to Sept., 1893).
Barometer (inches):		
Mean	29. 905	
Highest	30. 857 (Feb. 5)	
Lowest	29. 113 (Oct. 14)	
Temperature (° F.):		
Mean	47. 6	62.
Highest	92 (June 20, Aug. 11)	92 (June 20, Aug. 11).
Lowest	—7 (Jan. 18)	29 (Apr. 11).
Annual range	99	21. 1.
Mean daily range	19. 1	43 (Aug. 5, Sept. 5).
Greatest daily range	43 (Aug. 5, Sept. 5)	
Least daily range	3 (Jan. 28, Mar. 23)	
Mean daily relative humidity (per cent)	78. 2	72. 95.
Rainfall (inches):		
Total	42. 2	24. 99.
Greatest monthly	64. 6 (May)	
Greatest daily	1. 6 (Aug. 29)	1. 60 (Aug. 29).
Number of days on which 0.01 in. or more of rain fell.	135	69.
Mean percentage of cloudiness	60. 95	55. 8.
Number of days on which cloudiness averaged 80 per cent or more.	152	66.
Average hours of sunshine per day		5 h. 56 min.
Wind (miles):		
Total movement	32, 700	
Maximum velocity	40 (Feb. 19)	
Greatest daily movement	425 (May 4)	
Last frost in spring		May 8.
First frost in fall		Sept. 27.

Principal periods of crop development.

Wheat:
- Sown September 5-12, 1892.
- In bloom June 9, 1893.
- Ripening June 23.
- Harvested July 14-21.

Corn:
- Planted May 19.
- In silk August 4.
- Cut September 8 to October 6.
- Husking began October 6.

Oats:
- Sown April 24.
- Ripening July 28.
- Harvested August 4.

Potatoes:
- Planted May 19.
- Harvested (late varieties) September 8 to 29.

Grass:
- In bloom June 23.
- Hay cut June 30 to July 14.

Clover:
- Cut June 23.
- Second crop in bloom August 4.

"The weather in general pleasant, but marked departure from the average. For the year as a whole, the minimum temperature was somewhat below the usual figure, and the mean daily range a trifle high. The total rainfall was somewhat above the average, as was the cloudiness. For the winter season of 1892-'93 the mean temperature was low; while the snowfall was heavy, especially in February, the winter was dry and cisterns were emptied. During the growing season of 1893 the mean daily range of atmospheric temperature was a trifle above the average, but that of the soil further below the average. The rainfall was not excessive, and was fairly distributed; coming at haying and at spring plowing time, it retarded farm operations, while there was some drought in midsummer. In general, the year was cloudy. The hay crop was moderate, wheat good, oats a little light, and corn considerably below the average, it having suffered from summer drought. In spite of late planting, it matured fully as early as usual."

The distribution of storms on the surface of the globe (*Rev. Scientif., 10 (1895), No. 3, pp. 92, 93*).

The cause of the cyclones of the temperate latitudes, W. H. Dines (*Amer. Met. Jour., 11 (1895), No. 10, pp. 359-364*).—A discussion of Ferrel's convection theory and Hann's eddy theory, the weight of evidence being stated to be in favor of the former.

Recent foreign studies of thunderstorms, R. DeC. Ward (*Amer. Met. Jour., 11 (1895), No. 10, pp. 364-368*).—A brief review of recent reports of investigations of this subject in Russia.

Psychrometer studies, H. A. Hazen (*Amer. Met. Jour., 11 (1895), No. 10, pp. 371-373*).—A criticism of Ekholm's methods and results in this line.

Gulf storm notes, W. D. Stearns (*Amer. Met. Jour., 11 (1895), No. 10, pp. 368-371*).—Notes taken during the passage of the Gulf storm of October 4 to 11, 1894.

Meteorological summary for North Carolina for November, 1894, H. B. Battle, C. F. von Herrmann, and R. Nunn (*North Carolina Sta. Weather Service Bul. 62, pp. 171-183, charts 2*).—The usual summaries of observations by the State Weather Service coöperating with the Weather Bureau of this Department.

Mexican meteorological bibliography, R. Aguilar y Santillán (*Mem. Rev. Soc. Cient. "Antonio Alzate," 8 (1894-'95), No. 1 and 2, pp. 5-9*).—This is for the year 1893, uniform with similar bibliographies for preceding years by the same author, published in previous volumes of this journal.

Observations on dew and frost, R. Russell (*Naturwiss. Rundschau, 1893, No. 19, pp. 235-239; abs. in Centbl. agr. Chem., 23 (1894), No. 10, p. 697*).—The author reports independent observations which confirm the conclusions of a number of other investigators that dew and frost are largely produced by the aqueous vapor arising from the earth, and that the aqueous exhalations of plants also contribute to dew formation.

SOILS.

On the movement of water in the soil, MOORMANN (*Schilling's Jour. für Gasbeleuchtung und Wasserversorgung, 1894; abs. in Forsch. Geb. agr. Phys., 17 (1894), No. 5, pp. 449, 450*).—The principal point brought out in this paper is that in all soils water forms hydrates (termed by Graham and Mendelejeff hydrosols) which more or less completely fill up the soil pores and interfere with the circulation of water.

The fact that wet sand molded by the hand retains its shape after drying is an evidence that the water has developed a binding power which the sand did not previously possess. This can be explained in case of pure sand, it is claimed, only by the formation of a thin coating of hydrate of silica which binds the particles together. The finer the sand the greater the amount of this hydrate formed.

While this formation of hydrates in sand lessens the friction between particles and causes them to occupy less space, in case of close-grained dry clay it is so great that the clay increases in volume almost 15 per cent in absorbing the ordinary amount of soil moisture.

In support of the theory that water combines chemically with clay soils it is pointed out that moderately moist clay yields no water on pressure, and that moistening of clay generates an appreciable amount of heat and develops a peculiar odor, at the same time evolving gases. The influence that this formation of hydrates has on the circulation of the water of the soil depends, of course, upon the fineness of the soil particles and the amount of hydrates formed.

Soil temperatures, W. FREAR and W. S. SWEETSER (*Pennsylvania Sta. Rpt. 1893, pp. 174–181, 187, 223–246*).—A record is given of tri-daily observations during 1893 with thermometers at the surface and at depths of from 1 to 24 in.

The following is a summary of observations during the growing season:

Soil temperatures, April to September, 1893.

Depth.	Highest.	Lowest.	Daily mean.	Mean daily range.	Greatest daily range.
	Deg. F.	*Deg. F.*	*Deg. F.*	*Deg. F.*	*Deg. F.*
At surface	81.0 (June 20, July 4, Aug. 11).	33.0 (Apr. 2)	61.3	8.99	24.0 (Apr. 3, 8).
1 in. deep	81.0 (Aug. 11)	32.0 (Apr. 2)	60.4	8.44	23.5 (Apr. 8).
3 in. deep	76.5 (Aug. 11)	32.0 (Apr. 2, 3)	60.9	4.27	17.0 (May 30).
6 in. deep	76.0 (Aug. 11)	32.0 (Apr. 1, 2, 3)	60.1	2.86	9.5 (Apr. 8).
12 in. deep	73.0 (Aug. 11)	32.5 (Apr. 1, 5)	60.0	1.13	4.5 (Apr. 8).
24 in. deep	69.5 (Aug. 28, 29)	33.0 (Apr. 1–4)	58.5	0.25	1.5 (May 8, Sept. 12).

Analyses of soils, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 254–258*).—Analyses of 17 samples in addition to those reported in Bulletin 30 of the station (E. S. R., 5, p. 857) are tabulated and briefly discussed.

"Most of these soils have been under cultivation from 5 to 30 years.

"The first impression of the results would indicate that the weak point is in the potash content. . . . In many of these soils the total potash amounts to as much as 2.5 per cent, while the amount of potash soluble in acid amounts to only a little over 0.20 per cent. There is every indication . . . that much of the potash that is insoluble in the acid possesses agricultural value. . . .

"These analyses, as well as those reported in former publications, show that most of the typical soils of the State are well supplied with phosphoric acid. . . .

"There is a good content of lime in most of the typical soils of the State."

The action of organic and mineral acids upon soils, H. SNYDER (*Jour. Amer. Chem. Soc., 17 (1895), No. 2, pp. 148–151*).—Comparative tests of the solvent action of hydrochloric acid of 1.115 sp. gr.; 10 per cent solutions of citric, oxalic, and tartaric acids; and a 10 per cent mixture of the last three, were made on the same sample of soil. The digestion was carried on for 36 hours in the Snyder soil flask (see p. 689). The results obtained were as follows:

Solvent action of hydrochloric and organic acids upon soil.

	Hydrochloric acid 1.115 sp. gr.	Ten per cent solution of—			
		Citric acid.	Oxalic acid.	Tartaric acid	Organic acid mixture.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Total insoluble matter	84.08	87.90	85.07	87.67	85.93
Potash	0.30	0.12	0.18	0.06	0.10
Soda	0.25	0.17	0.19	0.05	0.12
Lime	0.51	0.50	0.23	0.41	0.45
Magnesia	0.26	0.27	0.21	0.32	0.33
Iron oxid	2.56	1.59	1.14	1.62	2.23
Alumina	4.24	1.45	3.96	1.77	2.99
Phosphoric anhydrid	0.23	0.26	0.14	0.11	0.26
Sulphuric anhydrid	0.08	0.10	0.05	0.06	0.05

"The oxalic acid possesses the greatest solvent action upon the complex insoluble matter of an alkaline nature. The citric acid possesses the greatest solvent action upon the lime, magnesia, and the sulphuric and phosphoric anhydrids. The amount of lime dissolved by the oxalic acid is greater than would at first be expected, but the complex nature of the solution and the presence of the salts of other metals has caused nearly half as much lime to be dissolved by the oxalic acid as by the hydrochloric acid of 1.115 sp. gr.

"The 10 per cent mixture of the 3 organic acids has resulted in dissolving as much phosphates and magnesia and nearly as much lime as any one of the acids acting alone. The potash does not appear to be as soluble in the organic acid mixture as the other elements of plant food.

"The amount of potassium, iron, and aluminum oxids dissolved by these 3 organic acids and their mixtures is somewhat less than that dissolved by the hydrochloric acid. . . . The main difference between the solvent action of the hydrochloric and the organic acids is in the somewhat smaller amount of potash dissolved by the organic acids.

"With the exception of the solubility of the potash, as noted, these results bring out in a general manner the value of hydrochloric acid of 1.115 sp. gr. as a solvent over the organic acids of 10 per cent strength, because the hydrochloric acid represents the limit of the solvent action reached by any one of the organic acids acting alone or in a mixture."

The solvent action of concentrated mineral acids, hydrochloric, nitric, and sulphuric, was tested on the same sample of soil and compared with the results obtained by the fusion method.

"Concentrated hydrochloric acid, 40 per cent strength, dissolved 2¼ per cent more of the complex silicates than nitric acid of the same strength. Concentrated nitric acid possesses a stronger solvent action than the dilute hydrochloric acid. The concentrated hydrochloric acid dissolved somewhat more potash than the hydrochloric acid of 1.115 sp. gr. The amount of lime, phosphates, and sulphates dissolved by the concentrated hydrochloric acid was about the same as when the more dilute acid was used; the concentrated acid, however, dissolved more of the complex silicates of potash, iron, and alumina. Sulphuric acid possesses the strongest solvent action.

"Of the total potash in the soil as determined by fusion, less than 18 per cent is soluble in the hydrochloric acid as used in soil analysis; about 10 per cent is soluble in oxalic acid, and 3 per cent in tartaric acid."

The chemical analysis of the soil in its relation to fertilizer experiments, VON LIEBENBERG and E. VON PROSKOWETZ, Jr. (*Mitt. Ver. Förd. landw. Versuchw. Oesterr., 1894, No. 9, pt. 1, pp. 23–35*).—As in the two previous years (E. S. R., 5, p. 702), the soil of plats containing 100 square meters on which fertilizer experiments on barley and oats were made was carefully sampled and analyzed and the results of analysis compared with the action of the fertilizers employed. In previous analyses only the phosphoric acid and nitrogen were determined, while in the present case potash soluble in nitric acid was also estimated. The results in general confirm those of previous investigations. Nitrogen was found to be as a rule more abundant in the soil than in the subsoil. The relation of phosphoric acid in the soil and subsoil was variable, being influenced evidently by the previous system of culture and manuring. The same was true in general of the potash. In the heavy soils used the potash was in almost every case considerably higher than the phosphoric acid and frequently higher than the lime. The soils are therefore much benefited by calcareous manures.

The experiments with barley indicated that in unfertilized soil the yield varied directly with the amount of nitrogen present. As in previous years, the yield was greater the greater the proportion of nitrogen to phosphoric acid, provided a sufficient amount of phosphoric acid and potash was present. The ratio of phosphoric acid to nitrogen in the first series of soils was 1 to 1.38, in the second series 1 to 1.06. In almost every case the soils responded to applications of nitrate of soda, although the soils contained amounts of nitrogen varying from 17 to 84 kg. per 100 square meters of soil.

With phosphatic fertilizers the results were irregular, but as a rule they were effective on barley on soils containing an average of 24.5 kg. of phosphoric acid in 100 square meters of the surface soil, and on oats on soils containing an average of 23.4 kg. It is concluded that on soils containing more than about 40 kg. of phosphoric acid per 100 square meters of surface soil manuring with phosphates is of doubtful value or entirely useless for cereals, unless accompanied by heavy applications of nitrogenous fertilizers. This limit of profitable application of phosphatic manures will be exceeded or fallen short of according to the availability of the phosphoric acid of the soil, the season, etc.

The season was such and the number of experiments with potash so small that no definite conclusions as to the limit of profitable potash fertilizing can be drawn, but it is shown with considerable certainty that the limit is considerably higher than with phosphatic manures. It appears also that for cereals soils must contain more lime than potash in order that potash fertilizing may be profitable.

The conservation of nitrates in the soil (*Jour. Agr. Prat., 59 (1895), No. 4, pp. 144, 145*).—A brief summary of Dehérain's results.

The available plant food in soils (*Jour. Bath and West of England Soc., 4 (1893–'94), ser. 4, pp. 212–215*).—A brief review of an article by B. Dyer on this subject.[1]

The composition of native and cultivated soils and the effects of continuous cultivation upon their fertility, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 163–191*).—A reprint of Bulletin 30 of the station (E. S. R., 5, p. 857), with the addition of brief notes on the collecting and forwarding of soil samples.

The management of clay farms, W. F. BROWN (*Cult. and Country Gent., 70 (1895), No. 2195, pp. 143, 144*).—Notes on cultivation on clay land in Ohio, with advice as to its proper treatment.

FERTILIZERS.

Analyses and valuation of complete fertilizers, ground bone, and miscellaneous samples, E. B. VOORHEES, L. A. VOORHEES, and J. P. STREET (*New Jersey Stas. Bul. 104, pp. 46*).—This is the second of the two regular annual bulletins on fertilizers issued by the station. The main object of the first (Bul. 102; E. S. R., 6, p. 396) was "to show the sources and composition of the materials containing the best forms of nitrogen, phosphoric acid, and potash; the cost per pound of the ingredients; and the advantages of making home mixtures." The present bulletin gives analyses and valuation of 224 samples of mixed fertilizers, 29 samples of bone, 9 samples of wood ashes, and 17 samples of miscellaneous products, the main object being "to show whether the actual composition of the various products corresponds with their guaranty as required by law."

As a rule the fertilizers examined contained as much total plant food as was guaranteed, but in many cases "it was not distributed in the proportions stated in the guaranties, which indicate either a lack of skill or of carefulness in their preparation. In two cases only the consumer received less of all of the plant-food constituents than was guaranteed."

---

[1] Jour. Chem. Soc. London, 1894, Mar., p. 115 (E. S. R., 5, p. 1013).

"Ninety-six of the 224 brands, or 43 per cent, contained less phosphoric acid than was guaranteed; 27 brands contained less potash, and 20 less nitrogen. In the case of nitrogen particularly, the actual amount contained was in many cases greatly in excess of the guaranty.

"The chief difficulty in respect to keeping the guaranty was in the case of phosphoric acid.

"The average composition, selling price, and commercial valuation per ton of all the brands of mixed fertilizers examined in 1891, 1892, 1893, and 1894, as well as the percentage difference between valuation and selling price, or the charges for mixing, bagging, and selling, are shown in the following tabulation:

Average composition, selling price, and valuation of fertilizers.

	Total nitrogen.	Total phos. acid.	Available phos. acid.	Insoluble phos. acid.	Potash.	Selling price.	Station valuation.	Percentage difference.
1891	2.71	10.12	7.29	2.83	4.21	$34.23	$25.31	35.2
1892	2.74	10.38	7.70	2.67	4.50	34.19	25.66	33.2
1893	2.69	10.23	7.54	2.69	4.58	34.11	24.41	39.7
1894	2.87	10.40	7.37	3.03	4.94	34.17	24.83	37.6

"At the average cost per pound of the nitrogen, phosphoric acid, and potash in these fertilizers it would cost the farmer 36 cts. to return to the soil the fertilizing ingredients carried off in every bushel of wheat sold, 28 cts. to return the amount contained in a bushel of corn, 30 cts. to return that contained in a bushel of rye, 18 cts. for that contained in a bushel of oats, and $7.16 to return the fertilizer constituents removed in a ton of timothy hay. . . .

"It is clear that at these prices for plant food a very narrow margin is left to the farmer in the sale of crops for legitimate charges for labor of growing, hauling, selling, and other expenses."

Still it is maintained that the use of fertilizers is profitable, even under these conditions. It is recommended, however, to (1) reduce cost of plant food in mixed fertilizers by buying on the "unit"[1] basis; (2) limit exportation of fertilizing constituents from farms on which stock is kept "by a judicious exchange of grain and hay for concentrated feeds rich in the fertilizing constituents, coupled with careful saving and intelligent application of the manure made;" and (3) reduce the outlay for the expensive element nitrogen "by sowing larger areas of leguminous crops which gather nitrogen from the air." Crimson clover is considered especially valuable for this purpose.

"The samples of ground bone examined this year, on the whole, reached their guaranty, showed a good degree of fineness, and, with few exceptions, a relatively high valuation. A larger number than usual, however, belonged to the class 'steamed bone.' . . .

"The number of samples of wood ashes examined this year was somewhat larger than usual, and they showed the usual wide variation in composition. . . . With but one or two exceptions the prices charged for the plant-food constituents were excessive."

Fertilizing with phosphoric acid as a means of producing cheap nitrogen, P. WAGNER (*Deut. landw. Presse, 22* (*1895*), *No. 1, pp. 5, 6, figs. 3*).—Pot experiments with fertilizers on oats, peas, and vetches are reported, illustrating especially the difference in the relation of leguminous plants and cereals toward nitrogen. It appears from these experiments that potash and phosphoric acid were without effect on oats except when used in connection with nitrogen. On the other hand, they exerted their full effect on the peas and vetches without the addition of nitrogen. The yields on the pots under different methods of fertilizing were as follows:

---

[1] One per cent per ton or 20 lbs.

Yields of oats, peas, and vetches with different fertilizers.

	Without nitrogen.			With nitrogen.		
	Oats.	Peas.	Vetches.	Oats.	Peas.	Vetches.
	Grams.	*Grams.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*
With potash and phosphoric acid	29	317	287	415	376	332
Without potash and phosphoric acid	32	131	85	126	159	126
Increase due to potash and phosphoric acid	−3	186	202	289	217	206

The oats grown on the unfertilized soil and on the soil fertilized only with potash and phosphoric acid contained on the average 0.23 gm. of nitrogen per pot; while the peas grown on the unfertilized pot contained 2.02 gm. of nitrogen, and on the pot fertilized with potash and phosphoric acid 6.11 gm. of nitrogen. The results plainly show that potash and phosphoric acid were without effect on cereals except when a supply of soluble nitrogen was present in the soil or was furnished in the fertilizer, but that they were effective on leguminous plants when the nitrogen was deficient, because these plants assimilate the nitrogen of the air.

From these experiments it appears that for each 100 kg. of phosphoric acid which the soil or the fertilizer furnishes to vetches 400 kg. of atmospheric nitrogen is collected and stored up in the plant tissue; while for each 100 kg. of phosphoric acid furnished to oats 250 kg. of nitrogen is drawn from the soil or the fertilizer applied.

In order that leguminous plants may collect the maximum amount of nitrogen from the air they must be liberally fertilized with phosphoric acid (and, where necessary, with potash). This should be applied when the stubble is turned down and the leguminous crop seeded, or if the latter is seeded among the grain sufficient phospate should be applied to supply the needs of both crops. In no case should the leguminous crop be allowed to hunger for phosphoric acid. The quicker its needs in this respect are supplied the sooner and more rapidly it will collect nitrogen from the air.

The results of investigations of the cause of failures of alfalfa in certain fields of Laubenheim, on the Rhine, are cited as indicating that decline in thriftiness of leguminous plants on soils on which they have been grown continuously for several years may be due to exhaustion of the soil in available phosphoric acid.

Investigations on the foraging powers of some agricultural plants for phosphoric acid, W. BALENTINE (*Maine Sta. Rpt. 1893, pp. 13–25, pls. 21*).—The comparative capacity of wheat, barley, corn, beans, peas, potatoes, and turnips to utilize the phosphoric acid of insoluble phosphates (South Carolina rock) was tested as follows: For each kind of plant 9 wooden boxes 15 in. square and 12 in. deep, containing 120 lbs. of fine sand,[1] were used in 3 sets of 3 boxes each, fertilized as follows: Set I, 8.5 gm. nitrate of soda (1.36 gm. nitrogen), 2.6 gm. muriate of potash (1.36 gm. potash); Set II, 8.5 gm. nitrate of soda (1.36 gm. nitrogen), 2.6 gm. muriate of potash (1.36 gm. potash), 17 gm. South Carolina rock (3.96 gm. insoluble phosphoric acid and 0.39 gm. citrate soluble phosphoric acid); Set III, 8.5 gm. nitrate of soda (1.36 gm. nitrogen), 2.6 gm. muriate of potash (1.36 gm. potash), 28.5 gm. acidulated South Carolina rock (3.34 gm. soluble phosphoric acid, 0.50 citrate soluble phosphoric acid, and 0.62 gm. insoluble phosphoric acid).

The boxes were given proper care, and the crops were harvested at maturity; photographs, from which the plates in the article were made, being taken just before harvesting. The yields obtained were as follows:

Yields of dry matter by different crops.

	Yield of dry matter.		
	Set I.—No phosphate.	Set II.—Insoluble phosphate.	Set III.—Soluble phosphate.
	Grams.	*Grams.*	*Grams.*
Wheat	76.9	148.6	296.3
Barley	201.5	294.9	508.1
Corn	39.5	103.3	291.0
Beans	15.7	17.4	69.8
Peas	112.7	196.7	228.6
Potatoes	113.3	114.6	223.6
Turnips	154.4	304.1	270.4

"While it may not be desirable to draw definite conclusions from so small an amount of data as is furnished by the above-described experiments, there are some points which under the conditions of these experiments the results appear to bring out sharply.

"(1) Different crops showed a decided difference in their powers of obtaining phosphoric acid from crude, finely ground South Carolina rock. Wheat, barley, corn, peas, and turnips apparently appropriated the insoluble phosphoric acid from this source with greater or less ease, while beans and potatoes derived no benefit from it.

"(2) The greatest practical advantage derived from the use of finely ground South Carolina rock was with the turnips. With this crop a larger weight of dry matter and also a larger weight of fresh roots was obtained with insoluble phosphoric acid from the finely ground South Carolina rock than with an equal amount of soluble phosphoric acid from acidulated South Carolina rock.

"(3) The indications point to a profitable use of finely ground South Carolina rock as a manure for barley and peas as well as turnips."

---

[1] Containing 0.096 per cent of potash and 0.012 per cent of phosphoric acid.

It was incidentally observed in these experiments that "the acidulated South Carolina rock apparently depressed the yield of grain with barley while largely increasing the amount of straw; with wheat both grain and straw were largely increased and in about the same proportion." The figures obtained were as follows:

Effect of acid phosphate on proportion of grain and straw of wheat and barley.

	Set I.	Set II.	Set III.
	Grams.	*Grams.*	*Grams.*
Barley (air dry):			
Total crop	215	312	538
Grain	44	61	17
Wheat (air dry):			
Total crop	84	162	325
Grain	26	50	105

A partial chemical analysis (fertilizing constituents) is given of the total crop produced in each set of boxes.

Results of five years' experiments with fertilizers, W. C. STUBBS (*Louisiana Stas. Bul. 31, 2d ser., pp. 1092–1123*).—After an introduction discussing the forms of fertilizers used with a brief review of the latest investigations relating to the nature, care, and use of barnyard manure, and remarks on the value of leguminous plants in rotation, deductions drawn from five years' experiments with fertilizers for staple crops on three typical soils of the State are reported. The fertilizers which at one time or another have entered into these experiments are: *Nitrogenous fertilizers*—Stable and farm manures, composts with and without cotton seed and with and without acid phosphate, cotton seed (raw, crushed, and rolled), cotton seed meal, nitrate of soda, sulphate of ammonia, dried blood, fish scrap, and tankage; *Phosphatic fertilizers*—Dissolved boneblack, acid phosphate, precipitated dissolved bone, precipitated acid phosphate, bone meal, bone ash, floats, and iron slag; *Potassic fertilizers*—Kainit, muriate of potash, sulphate of potash, nitrate of potash, carbonate of potash, and cotton-hull ashes.

The chemical composition of the soils experimented on was as follows:

Composition of Louisiana soils.

The soil at Audubon Park is alluvial, very stiff, and is benefited by thorough drainage. "It is an excellent quality of 'mixed' soil." That at Baton Rouge is a brown loam belonging geologically to the Bluff formation. It is underlaid at varying depths by white chalky-looking clay. It is greatly benefited by drainage, but this is difficult to obtain on account of the conformation of the land. The Calhoun soils vary from yellow sandy clays to pure sand. "They are naturally very poor, but susceptible of rapid improvement and responsive to the smallest application of manures."

Experiments were made to determine the kind, form, and quantity of each of the fertilizing constituents required by sugar cane, corn, oats, and cotton at Audubon Park; cotton, corn, sugar cane, and potatoes at Baton Rouge; and cotton, corn, sugar cane, tobacco, and potatoes at Calhoun. Experiments have also been made to test the comparative merits of broadcast and drill applications and applications at different dates.

The results show "that the crying want of the Calhoun soils is nitrogen; that the soils of Audubon Park, under favorable seasons, will appropriate one to two rations of nitrogen with profit. Baton Rouge soils are responsive to nitrogen only when properly combined with phosphoric acid."

At Calhoun the order of effectiveness of the different forms of nitrogen was compost of cotton seed, stable manure, and phosphate; crushed cotton seed, nitrate of soda, cotton-seed meal, fish scrap, tankage, sulphate of ammonia, rolled cotton seed, and dried blood. At Audubon Park cotton-seed meal proved the most effective form, followed closely by sulphate of ammonia, fish scrap, nitrate of soda, tankage, and dried blood. At Baton Rouge sulphate of ammonia gave the best results, followed closely, however, by the other forms. It is stated in general that there was little preference in any of these forms of nitrogen. Nitrate of soda appeared to be most effective on light sandy soils, sulphate of ammonia on stiff clay lands.

"At Calhoun, upon thin soils, 1 ration (24 lbs.) of nitrogen is nearly the maximum quantity which crops can now appropriate. With improvement, these soils may digest and render available increased quantities. At Baton Rouge, with favorable seasons, 2 rations (48 lbs.) of nitrogen may be assimilated by the crops with profit, though on account of almost annual droughts, it is unwise to apply, as a rule, larger quantities than 1 ration (24 lbs.). Experiments at both of these stations have determined the above. At Audubon Park 2 rations (48 lbs.) can easily be assimilated by sugar cane in a fair season, provided the soil be well drained and cultivated, *i. e.*, in good tilth. Experiments have shown that 3 rations are excessive and always produce a waste. On cotton, corn, and oats less quantities of nitrogen will suffice. Irish potatoes, cabbage, etc., may easily dispose of with profit 72 lbs. (3 rations) of nitrogen per acre."

The experiments with phosphoric acid indicate "that the soils of Audubon Park and Calhoun require only small doses of phosphates mixed with strongly nitrogenous fertilizers to give remunerative returns, while the soils of Baton Rouge can consume goodly quantities with increased crop products." The soluble forms of phosphoric acid were invariably more profitable than the insoluble. Of the latter, slag meal was most effective, while bone meal in no case gave a profitable return.

"Neither at Calhoun nor Audubon Park have excessive quantities been beneficial. At the former perhaps 24 lbs. soluble phosphoric acid per acre is an abundance for any crop, while 1 ration (36 lbs.) has been found to be ample for the cane crop at the latter station at Baton Rouge. Upon the best character of soils and in favorable seasons 50 lbs. or more to the acre of this ingredient might be profitably applied to certain crops."

"No crop at any of the 3 stations has been benefited by the application of potassic salts."

The results of the experiments with the different methods of application indicated that—

"If the soil be very loamy or clayey and retains fertilizers well, perhaps little or no loss will occur by putting all the manure under the plant at the time of planting. But if the soil be sandy and inclined to 'leach,' fertilizers, particularly nitrogen compounds, should never be applied all at once under fibrous-rooted plants. Mineral fertilizers may be thus applied, since they leach but little, and even complete fertilizers may be thus used under quickly-growing tap-rooted plants. . . .

"Where the soil is open and porous and root development can occur without hindrance, then broadcasting may be done, with chances that the fibrous roots, permeating easily in every direction, may catch most of the applied fertilizers, but in very stiff, compact soils such extensive root development is impossible, and therefore much of the broadcast fertilizer will not be accessible to the roots of the growing crop. As a rule, then, it may be asserted that broadcasting is permissible upon hoed crops in light soils, but wasteful in stiff, heavy soils."

The results of experiments at Calhoun strongly favor 1 application at time of planting under cotton, but "strongly suggest the practice of making at least 3 applications of fertilizers for such plants as corn, cane, etc. At Baton Rouge little or no loss has occurred from 1 application at time of planting. . . . At Audubon Park experiments have been made similar to those discussed above, with 1, 2, and 3 applications, with as yet, no positive evidence against the prevailing custom of 1 application."

As regards the best depth of application "the consensus of results points unmistakably to the depth of 2 to 3 in. as producing the best results, and also shows the advantage of having all the ingredients combined at this depth."

Successful results with a rotation of oats, cowpeas, cotton, corn, and cowpeas are reported, and in conclusion tabulated data are given for experiments with fertilizers on sugar cane at Audubon Park for 1892 and 1893.

Soil tests with fertilizers in Virginia (*Southern Planter, 56 (1895), No. 2, pp. 79-81*).—The Virginia State Board of Agriculture, at its meeting January 8 to 10, 1895, adopted resolutions appropriating a sum not exceeding $1,500 for the purpose of conducting soil tests with fertilizers, not more than $150 of which is to be expended in any one Congressional district. This money is placed under the control of the Commissioner of Agriculture and the members of the State Board of Agriculture from the different districts in which experiments are made. The services of a scientist to aid in selecting and laying out plats, supervising the experiments from time to time, and preparing reports of results are to be secured through the Virginia Agricultural and Mechanical College, or from some other source, provided such services can be procured for a sum not exceeding $500.

The general plan of the experiments is to be that adopted by the convention of directors of experiment stations at Washington, March, 1889.[1] The experiments are to be made "chiefly in those sections of the State where the exhaustion of the soil and the depressed conditions of agriculture indicate their need."

On what kind of soils, to what crops, and in what forms should lime be applied, B. SCHULTZE (*Braunschw. landw. Ztg., 62 (1894), No. 51, pp. 213, 214*).—A popular article in which the draft of different crops on the lime content of the soil, the variation in lime content of different soils, the influence of chemical fertilizers in causing loss of soil lime, the indirect fertilizing action and physical effect of lime, and the comparative merits of marl, gypsum, and burnt lime are discussed.

Development of the natural sources of nitrogen (*Landw. Centbl. Posen, 23 (1895), No. 2, p. 8*).

The utilization of night soil as a fertilizer, J. H. VOGEL (*Deut. landw. Presse, 22 (1895), No. 8, pp. 66, 67*).

The town sewage question in its agricultural relations, R. S. BURN (*Jour. Bath and West of England Soc., 4 (1893-'94), ser. 4, pp. 106-117*).—A general discussion of this subject, critically reviewing present English systems of sewage disposal and urging the advisability of more extended use of city sewage in liquid form on farm lands.

On Kühn's views on the value of barnyard manure nitrogen, P. WAGNER (*Deut. landw. Presse, 22 (1895), No. 8, pp. 62, 63; No. 10, p. 83*).

The rational use of bone meal, M. ULLMANN (*Jour. Soc. Agr. Brabant; L'Engrais, 10 (1895), No. 5, pp. 113, 114*).—A brief popular summary of information as to the soils best adapted to bone meal and the best methods and time of application.

A new potash deposit (*Landw. Centbl. Posen, 23 (1895), No. 2, p. 9*).—The discovery is announced of a potash deposit on the boundary of Beyenrode, near Gifhorn, Hanover. It is a bed of kainit 20 to 30 meters thick and containing 27 per cent of chlorid of potassium. The deposit is calculated to contain 2,400,000,000 centner (about 132,000,000 tons) of the salt.

Commercial fertilizers, W. L. HUTCHINSON (*State Chemist Mississippi Bul. 6, pp. 12.*)—Notes on valuation and tabulated analyses and valuations of 37 official samples of fertilizers sent to the inspector by manufacturers, with a list of manufacturers' guaranties.

FIELD CROPS.

Millet, A. A. CROZIER (*Michigan Sta. Bul. 117, p. 64, figs. 6.*)

Synopsis.—The principal topics treated are the following: Character of soil; amount of seed; draft on soil fertility; curing, soiling, and pasturing millet; effect of millet hay on health of animals; weight, price, and uses of millet seed; diseases and enemies of millet; descriptions of cultivated forms or varieties, and yields of different kinds of millet.

In 1894 there were sown at the station 73 samples of millet seed, including 16 species and varieties. The dry season materially reduced the yields and altered the normal ripening period of the different varieties. Millet thrives best on a warm, loose, fertile soil. Where the soil is poor or where droughts prevail, broom corn millet and common millet are recommended as preferable to German millet; the first mentioned is specially recommended as resistant to drought.

The following table gives the yields of Hungarian grass hay on thirty second-acre plats on light, sandy soil and on loam when 1, 2, 4, and 6 pecks of seed per acre were sown:

---

[1] Office of Experiment Stations, Circulars 7 and 8.

Effect of amount of seed on yield of Hungarian grass hay.

	On light, sandy soil.	On heavy loam.
	Pounds.	*Pounds.*
One peck	70	65
Two pecks	41	78
Four pecks	42	74
Six pecks	39	49

Light seeding gave the best results. On another series of plats 3 pecks of seed per acre proved too much for all kinds of millet except broom corn millet, which has relatively large seeds. The author regards 2 pecks of seed as enough on ordinary soils for Hungarian grass, common millet, and German millet. For the production of seed 1 peck sown broadcast, or less if sown in drills, is recommended for all varieties except broom corn millet, of which 3 pecks is preferred.

As a crop for subduing weeds millet is regarded as superior to buckwheat. Millet has been satisfactorily used for soiling and pasturage. For pasturing Hungarian grass is preferred to common millet and German millet. Both timothy and a mixture of clover and timothy failed when sown with millet June 12.

Numerous quotations, representing conflicting opinions, are given as to the effect of millet hay on the health of live stock, especially of horses.

The diseases and enemies of millet are given as sorghum blight (*Bacillus sorghi*), millet smut (*Ustilago segetum* var.), and the chinch bug. Millet has been successfully used as a trap crop for this insect.

Common millet (*Setaria italica*) is small and early. Each root produces numerous slender stems with nodding, tapering heads, moderately compact above but loose at the base. The color of the heads is green, turning to a yellowish brown when ripe. The seeds are large, yellow, and oval.

Hungarian grass (*S. italica germanica*) is medium in maturity and has several stems from each root, erect or nearly erect heads, oblong, dark purple, bristly, and very compact; seeds oval, purple, mixed with yellow immature grains.

German millet (*S. italica*) is relatively late, has single or few large stems from each root; the head is usually nodding, and has purplish awns. The seeds are small, round, and yellow or golden.

Broom corn millet (*Panicum miliaceum*) has panicles resembling those of broom corn and generally grows about 2 feet high. It usually yields less fodder than other sorts, but is valuable both for forage and for seed in portions of the Northwest having short and dry seasons. "It stands drought remarkably well and is better adapted than any other kind to dry climates and poor soils."

Several cultural varieties of broom corn millet were grown, among them Japanese millet, which suffered from drought, but gave the largest yield of forage among the varieties of this group.

Golden Wonder millet (*S. italica*) has very long, tapering heads, with small green or sometimes rose-colored bristles. It is easily affected by drought, and rather late in maturing.

Other kinds of millet described are Missouri millet, California millet (*Setaria italica*), Italian millet (*S. italica*), Japanese millet (*S. italica*), Texas millet (*Panicum texanum*), sprouting millet (*P. proliferum geniculatum*), barnyard grass (*P. crusgalli*), sorghum (*Andropogon sorghum*), Johnson grass (*A. halapense*), and pearl millet (*Pennisetum typhoideum*).

A list of other species to which the name millet has also been applied is given. Tabulated data give number of seeds per gram, shape and size of seeds, and brief notes on the growth of all samples of millet tested.

On the quality of barley grown under different conditions, C. KRAUS and A. STELLWAAG (*Ztschr. landw. Ver. Bayern, 1894, pp. 164–171; abs. in Centbl. agr. Chem., 23 (1894), No. 10, pp. 667–670*).—As the barley grain becomes ripe its composition improves, the percentage of starch increasing and that of nitrogen decreasing. Heavy manuring, when it was accompanied by lodging of the straw, resulted in the formation of light grains with a high percentage of nitrogen and a low starch content. Among the barley grains of a single variety those were most glassy which contained a high percentage of protein, but the protein content was not the only factor concerned.

Cañaigre, E. W. HILGARD (*California Sta. Bul. 105, pp. 1–9*).—This is largely a résumé of all investigations heretofore published by the stations which have tested this crop. It appears that the deeper the tint of the foliage and the root the larger the percentage of tannin in the root, a fact which suggests possible improvement in cañaigre as has been effected in the case of the sugar beet. A comparison of the probable profits in growing black wattles and cañaigre is given, the result of the comparison being somewhat in favor of cañaigre. The following table gives the composition of the ash of cañaigre root, and for comparison the composition of the ash of the sugar beet:

Composition of ash of cañaigre root and sugar beet.

	Cañaigre.	Sugar beet.
	Per cent.	*Per cent.*
Silica	3.89	3.50
Potash	28.74	49.40
Soda	2.47	9.60
Lime	8.16	6.30
Magnesia	16.93	8.90
Brown oxid of manganese	0.98	....
Peroxid of iron and alumina	2.45	1.10

Chlorin	6.43	2.60
	101.40	100.40
Excess of oxygen due to chlorin	1.40	0.57
Total	100.00	99.83
Percentage of pure ash in dry root	4.48	4.35
Percentage of crude ash in dry root	4.79	5.44
Percentage of carbonic acid in crude ash	5.20	20.00
Percentage of total nitrogen in dry root	1.93	0.87

"Roughly speaking, we are probably justified in assuming that for equal weights of crop the cost of replacing the mineral soil ingredients by the purchase of fertilizers when necessary, will be about the same for both crops (cañaigre and sugar beets); while as regards nitrogen, our determination shows that the cañaigre draws nearly twice as heavily as the beet, so that a crop of 10 tons of fresh roots will take out of the soil nearly 100 lbs. of nitrogen per acre. In regular culture it should, therefore, probably be alternated with leguminous crops, that enrich the soil in nitrogen."

Corn as a silage crop, W. H. JORDAN (*Maine Sta. Rpt. 1893, pp. 57–63*).—This article contains the results of a comparison of silage made from Southern corn and Maine field corn, previously published as Bulletin 11 of the station (E. S. R., 6, p. 34), and a study of the ripening of silage corn. On each of 10 twentieth-acre plats one fifth of the area of corn was cut at 5 different dates. The following table gives the yield of green corn and of dry matter resulting from harvesting the crop at different stages of growth:

Yield of green corn and dry matter in an acre of corn at different stages of growth.

Date of cutting and condition of crop.	Days in each period of growth.	Yield of green corn per acre.	Dry matter.		Gain in weight in each period.	Rate of gain per day.
			In crop.	Yield per acre.

[1] The manner of drying the sample taken from the lot cut at this period may have caused a loss of sugar.

"Two facts are clearly shown: First, that the later growth of dry matter in the corn plant is made up chiefly of non-nitrogenous compounds; and second, a large percentage of these compounds consisted of sugars and starch, substances that are the best of their class for the purposes of animal nutrition."

Variety tests of oats, H. J. WATERS and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, pp. 116, 117*).—Fifteen varieties were tested in 1893 on duplicate twentieth-acre plats. Tabulated data give yields for each year of all varieties tested. The average yields per acre for 1890, 1891, 1892, and 1893 were as follows:

Average yield per acre for 4 years of varieties of oats.

Variety.	Bushels.	Variety.	Bushels.
Baltic White	43.62	Early Russian	37.13
Japan	42.62	Henderson Clydesdale	36.89
Improved American	42.35	Welcome	35.59
German	41.03	Des Flandres	34.27
Scottish Chief	40.91	Jaune des Flandres	32.75
Wide Awake	39.13	White Bonanza	32.52
White Victoria	37.89	White Wonder	30.06
Haggett White Seizure	37.14		

Influence of maturity upon the yield of dry matter in soiling rye, H. J. WATERS (*Pennsylvania Sta. Rpt. 1893, pp. 52–54*).—This experiment was conducted on 9 plats each 6 by 100 ft. On 3 plats rye was cut just before heading, May 19; on 3 plats it was harvested when three quarters headed, May 24; on the other plats the crop was cut when in blossom, May 31. The rye cut before heading yielded 1,624.94 lbs. of dry matter per acre; that three quarters headed 2,702.79 lbs.; and that cut when in blossom 3,763.94 lbs. Assuming that the 3 lots of rye were equally digestible, the calculated yield of digestible matter per acre was as follows:

Yield of digestible matter per acre in rye cut at different stages of growth.

State of maturity.	Dry matter.	Ash.	Protein.	Fiber.	Nitrogen-free extract.	Fat.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
Before heading	1,189.3	68.58	160.29	369.1	555.3	36.05
Three fourths headed	1,986.5	96.22	212.54	696.0	937.0	44.71
In blossom	2,780.8	133.61	248.45	1,161.0	1,180.3	57.43

As much digestible dry matter was produced by 1 acre of rye cut when in bloom as by 2.34 acres cut 12 days previously and just before heading.

Australian salt bush, M. E. JAFFA (*California Sta. Bul. 105, pp. 10–16*).—The Australian salt bush (*Atriplex semibaccata*), grown at the Tulare Substation on some of the worst alkali spots on the grounds, yielded at the rate of about 5 tons of dry matter per acre. It is readily propagated by seed. Sheep and hogs eat the green plant readily, and horses and cattle soon get accustomed to it when mixed with other food at first. The following table gives the proximate composition of this plant:

Composition of Australian salt bush.

	Fresh.	Air-dried.	Water-free.
	Per cent.	*Per cent.*	*Per cent.*
Moisture	78.03	7.05	....
Albuminoids	2.75	11.64	12.53
Nitrogen-free extract	10.41	44.05	47.39
Fat	0.48	2.01	2.16
Fiber	3.75	15.88	17.08
Ash	4.58	19.37	20.84
Total	100.00	100.00	100.00

"The preceding analyses prove that this fodder is one of considerable merit."

The following table gives the composition of the ash:

Composition of the ash of Australian salt bush.

	Per cent.
Silica	16.24
Potash	11.42
Soda	35.39
Lime	5.79
Magnesia	3.23
Peroxid of iron	1.38
Alumina	1.95
Brown oxid of manganese	0.22
Phosphoric acid	2.80
Sulphuric acid	2.64
Chlorin	24.33
	105.35
Excess of oxygen due to chlorin	5.35
Total	100.00
Per cent of pure ash in air-dried substance	19.37

Although a ton of the air-dried plant contains nearly 14 lbs. of potash and 3½ lbs. of phosphoric acid, the fertilizing value of the ashes is more than balanced by the large amount of injurious alkali which it contains. A crop of 10,000 lbs. of dry salt bush removed 21.3 lbs. of potash, 5.93 lbs. of phosphoric acid, and 18.60 lbs. of nitrogen from the soil. By analyzing the alkali spots on which the plant was grown and the crop itself, it was found that a single crop of Australian salt bush removed 2.5 per cent of the total potassium sulphate in the soil, 2.99 per cent of the sodium chlorid, and 2.21 per cent of the sodium carbonate. "Soils where the percentages of alkali are near the limit of tolerance can no doubt be sensibly relieved by planting the salt bush and permanently removing each cutting from the land."

Fertilizer experiments with tobacco, W. FREAR (*Pennsylvania Sta. Rpt. 1893, pp. 82–112*).

Synopsis.—This is a report of progress on an experiment conducted by the station in coöperation with the Lancaster County Tobacco Growers' Society. Tabulated data give the yields of unfermented tobacco; the results are discussed at length.

General discussions on the tobacco crop, on the soil and climate of Lancaster County, and on the theory and practice of manuring the crop precede an account of the experiments conducted in 1893 at 2 localities in Lancaster County.

The questions investigated were: (1) Effects of phosphoric acid on limestone soils; (2) relative values of sulphate of potash and double carbonate of potash and magnesia; (3) cotton-seed meal, linseed meal, horn meal, and mixed cotton-seed meal and nitrate of soda as sources of nitrogen in complete fertilizers; (4) relative values of stable manure and chemical fertilizers; and (5) profit from the use of the above-mentioned fertilizers.

"As a basis of comparison it was determined that with a single exception all the artificial fertilizers should have the following composition:

	Per cent.	Pounds per acre.
Nitrogen	4.75	95
Phosphoric acid (available)	7.75	155
Potash (water soluble)	7.75	155

"This corresponded to the composition and quantity recommended for use in the case of one of the most popular tobacco manures."

This formula was of necessity not strictly followed in 1893. The fertilizers used cost at retail prices $27.22 to $41.77 per acre.

At Donegal the experiment occupied 20 twentieth-acre plats and at Rocky Springs 10 twentieth-acre plats, using duplicate plats in both localities.

At Donegal the soil was a limestone clay; the surface soil was 6 or 7 in. deep, and the subsoil a heavy yellow clay. Drought obscured the results. However, phosphoric acid appeared to increase the yield of leaf and of wrapper leaf. Double carbonate of potash and magnesia gave a slightly larger yield than sulphate of potash. The results from cotton-seed meal were regarded as slightly more favorable than those from linseed meal. Nitrate of soda (one-half applied interculturally) appeared to reduce the yield of wrappers. Barnyard manure showed no superiority over commercial fertilizers.

At Rocky Springs the soil was thin and "gravelly," belonging in the limestone class. Drought and hail vitiated the results. Here phosphoric acid was without marked effect.

The yield and quality of the fermented tobacco and the results of the chemical studies on the crops are to be published later.

Experiments with wheat, H. J. WATERS and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, pp. 112–115, dgm. 1*).—These consisted of tests of varieties and of seed selected by hand in comparison with that from the threshing machine. No marked differences in yield resulted from the 2 classes of seed. On duplicate twentieth-acre plats 26 varieties of wheat were tested in 1892 and 33 varieties in 1893. Tabulated data give yields of every variety for each year tested. The average yields per acre for 1890, 1891, 1892, and 1893 were as follows:

Average yields of different varieties of wheat for 4 years.

The culture of autumn catch crops, P. P. DEHÉRAIN (*Ann. Agron., 21 (1895), No. 1, pp. 5–16; abs. in Compt. Rend., 120 (1895), No. 2, pp. 59–64*).—The author had previously shown[1] that on soil kept entirely bare of vegetation the loss of nitrates through the drainage water was very considerable. In practice, however, after the removal of a grain crop, weeds and shelled grain germinate and afford some vegetation during the autumn. Hence he compared the amounts of nitrates lost in the drainage water of land covered with grass and that on which a crop of clover was growing. With grass the loss per hectare during the autumn of 1893 was 13.78 kg., with clover 22.18 kg. This heavy loss with both kinds of vegetation was attributed to the dryness of the summer of 1893 and to the fact that when the autumn rains came the plants were too feeble to appropriate all of the nitrates at their disposal. In 1894 the drainage water from the grass pots contained 9.76 kg. of nitric nitrogen per hectare, that from the clover pots 15.63 kg.

The office of catch crops is twofold, to take up nitrates during their growth and to supply nitrogenous matter to the soil after being plowed under. From the preceding figures grass was more active than clover in preventing the escape of the nitrates. However, clover when plowed under afforded 79.59 kg. of nitric nitrogen per hectare, while rye grass furnished only 55.15 kg., thus showing the superiority of clover as a crop for green manuring.

An investigation by M. Bréal confirmed the above results. He found in 1 kg. of soil which received no green manure 141 mg. of nitric nitrogen; in the same amount of soil in which rye grass had been turned under, 190.8 mg.; and in the same amount of soil in which alfalfa had been turned under, 289.4 mg.

In 1894 vetch sown on stubble in August and plowed under late in October or November afforded 78 to 90 kg. of nitric nitrogen per hectare, which is estimated as equal to 15,600 to 18,000 kg. of manure.

It was found that the dry matter of the roots of wheat contained a larger percentage of nitric nitrogen than that of rye grass and much more than that of clover.

The effect of chlorin compounds on yields of peas, grains, and potatoes, and on the starch content of potatoes, J. SCHULTE (*Magdeb. Ztg., 1894, No. 244; abs. in Centbl. agr. Chem., 23 (1894), No. 10, pp. 706, 707*).—The following chemicals were applied to peas, rye, barley, and potatoes: Calcium chlorid, magnesium chlorid, sodium chlorid, magnesium sulphate, and potassium sulphate. None of these chemicals reduced the yield of grain nor the percentage of starch in the potato tubers. Indeed, the yield of potato starch on the plat to which magnesium chlorid was applied was somewhat larger than on the untreated plat.

Fertilizer experiments on corn, oats, wheat, and grass, H. J. WATERS and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, pp. 65–81*).—

---

[1] Ann Agron., 19 (1893), No. 7, pp. 305-338 (E. S. R., 5, p. 419).

This is a report on rotation experiments with corn, oats, wheat, and timothy and clover on 4 series of 36 eighth-acre plats, commenced in 1881.[1] All fertilizers were applied annually. Nitrogen was supplied at the rate of 24, 48, and 72 lbs. per acre in the form of dried blood, nitrate of soda, or sulphate of ammonia; also as barnyard manure, the amount of nitrogen in the latter not being determined. Phosphoric acid was supplied at the rate of 48 lbs. per acre in the form of dissolved bone-black. Potash was furnished at the rate of 100 lbs. per acre in muriate of potash. Gypsum, lime, ground limestone, and ground bone were also used in a few instances.

Tabulated data give for each plat the yields of corn, stover, oats, oat straw, wheat, wheat straw, and hay for 1892 and 1893, and the average yields of the 12 years during which the experiment has been in progress.

The following table gives the average increase in yield of the different crops during 12 years with complete fertilizers containing 24 lbs. per acre of nitrogen in different forms, and with complete fertilizers containing 24, 48, and 72 lbs. of nitrogen per acre:

Average increase in yield for 12 years with different fertilizers.

Fertilizer.	Corn.	Wheat.	Oats.	Timothy and clover.
	Bushels.	*Bushels.*	*Bushels.*	*Pounds.*
Dried blood and minerals	6.93	3.76	6.21	−80
Nitrate of soda and minerals	10.53	4.80	6.04	473
Sulphate of ammonia and minerals	13.28	5.90	6.54	666
24 lbs. of nitrogen and minerals	7.35	2.49	5.51	681
48 lbs. of nitrogen and minerals	8.73	5.03	7.03	545
72 lbs. of nitrogen and minerals	12.17	6.15	6.23	508
Barnyard manure	8.52	3.17	5.68	395

Notes on plants distributed by the station, E. J. WICKSON (*California Sta. Bul. 106, pp. 8, figs. 2*).—Brief descriptive notes on the most important plants distributed are given. *Polygonum sachalinense* "is a coarse plant and is not advocated as a substitute for well-known forage plants where the latter are satisfactory. For dry lands scant of useful growth the plant is commended for trial. It has a perennial root which withstands both drought and freezing of the ground." Australian salt bush (*Atriplex semibaccata*) made in Tulare County a wonderful growth on strongly alkaline soil. The flat pea (*Lathyrus sylvestris*), from reports received from growers, appears to be much valued in some parts of California. The following forage plants have been found the most satisfactory for dry soil, but are not offered as substitutes for better plants on naturally moist land: Tall oat grass (*Arrhenatherum avenaceum*), Schrader's brome grass (*Bromus unioloides*), Hungarian brome grass (*B. inermis*), Japanese wheat grass (*Agropyrum japonicum*), many-flowered millet grass (*Milium multiflorum*), hairy-flowered paspalum (*Paspalum dilatatum*), and Texas blue grass (*Poa arachnifera*).

---

[1] See also Report of the Station for 1890, p. 124 (E. S. R., 3, p. 718).

The square-pod pea (*Lotus tetragonolobus*) is an annual leguminous plant which at the station on 2 different plats yielded at the rate of 24 and 26 tons of green material per acre. Other plants for distribution are Jesuits' tea (*Psoralea glandulosa*), Persian table grapes, Italian wine grapes, olive cuttings or scions, tree tomato of Jamaica (*Solanum betaceum*), cañaigre, rice, sugar cane, 2 varieties of beans, 1 of wheat, zigzag corn, and New England spinach (*Tetragonia expansa*).

Cultural methods for improving the yield of barley, M. HOLLRUNG (*Ztschr. landw. Ver. Hessen, 1894, No. 52, pp. 424, 425*).

Beets running to seed, RIMPAU (*Deut. landw. Presse, 21 (1894), No. 102, pp. 984, 985*).—A discussion of the influences which cause certain biennial plants to form seed stems during the first year of growth.

Cañaigre, B. M. LELONG (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 420–425, pls. 3, figs. 2*).—A general discussion of the culture of cañaigre (*Rumex hymenosepalus*), chiefly compiled from Arizona Station Bulletin 7 (E. S. R., 4, p. 804). Analyses of the root are given, and the plant and its roots and seeds are illustrated.

List of forage and miscellaneous plants under trial, O. LUGGER (*Minnesota Sta. Rpt. 1893, pp. 291–307*).—The author has under trial in small plats 546 forage and miscellaneous plants as follows: Grasses, 437 species; legumes, 92 species; and miscellaneous forage, textile, and oil-producing plants, 17 species. The object of the trials is to offer as many species as possible to the students for study and to ascertain what ones are adapted to the climate of the State. Nothing is given as to the relative value of the species tested.

Proximate analysis of upright brome grass (Bromus erectus), E. KINCH (*Agl. Students' Gaz., n. ser., 7 (1894), No. 2, p. 48*).

Sisal hemp in the Bahamas (*Kew Misc. Bul. 96, pp. 412–414*).

Fertilizer experiments on oats (*Agl. Students' Gaz., n. ser., 7 (1894), No. 2, pp. 39–42*).

Variety tests of potatoes, H. J. WATERS and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, p. 117*).—The yields and brief descriptive notes are given in the form of tables for 12 varieties tested on twentieth-acre plats. The most productive was Early Puritan, followed by Green Mountain and Empire State.

Variety tests and experiments with green manures for potatoes, CROCHETELLE (*Ann. Agron., 21 (1895), No. 1, pp. 17–34*).

Increasing the harvest by selecting seed potatoes, A. SEMPOTOWSKI (*Deut. landw. Presse, 22 (1895), No. 3, p. 21*).

The introduction of tobacco into France, E. ROZE (*Jour. Bot. France, 8 (1894), No. 21 and 22, pp. 375–380*).—An historical sketch.

Experiments with wheat, A. C. MAGRUDER (*Oklahoma Sta. Bul. 12, pp. 4*).—These consisted of tests of varieties, dates of sowing, and an experiment in manuring wheat. On the manured portion of the field the variety making the largest yield was Currell; on the unmanured portion, Sibley Hybrid. Stable manure largely increased the yield. Wheat was sown at intervals of one week from September 7 to the following January. The largest yield resulted from the sowing made September 21.

Chemical investigation of seed wheat and of the wheat plant, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 147–160*).—A reprint of Bulletin 29 of the station (E. S. R., 5, p. 867).

Experiments with wheat, oats, barley, corn, and potatoes, A. BOSS (*Minnesota Sta. Rpt. 1893, pp. 201–214*).—A reprint from Bulletin 31 of the station (E. S. R., 5, p. 1073).

Making silage by the use of Blunt's press, MÜLLER (*Ztschr. landw. Ver. Bayern, 84 (1894), Nov., pp. 868–872*).

HORTICULTURE.

Classification of the sexual affinities of Prunus americana vars., C. W. HEIDEMAN (*Expt. Sta. New Ulm, Minnesota, Rpt. 1894, pp. 10, pls. 2*).—This consists of a report of investigations upon the fertilization of plums, those used in the experiments being chiefly wild trees, although a few cultivated varieties were also employed. Numerous crosses were made, and a careful anatomical and physiological study of the pistils and anthers was undertaken, to determine the forms best adapted for self and cross fertilization and to ascertain the reasons of self and cross sterility. The flowers were found to fall in 3 groups, each with 2 subdivisions: Dichogamous, comprising proterogynous and proterandrous; Heterostyled, comprising long-styled and short-styled; and Bisexual, comprising gynodiœcious and andromœcious. The hermaphrodite form was found to be not common. The period of bloom usually lasts for 3 days to a week, although the actual time in the life of a blossom during which fertilization may be effected was found rarely to exceed 2 hours, beginning from 2 to 24 hours after the blossom has fully expanded.

The crosses between these various forms of flowers were found to vary greatly, in some cases not being possible. Reciprocal crosses were also found to vary in the intensity of fertilization. The term illegitimate is applied to such union of the reproductive elements as results in development of the ovary below the normal. Out of 49 possible combinations of pollination only 13 are considered legitimate, the others giving negative or but feeble results. Figures are given of the various forms of flowers and a diagram showing different ways in which fertilization can be accomplished.

Strawberry culture, W. B. ALWOOD (*Virginia Sta. Bul. 37, pp. 13–19*).—Descriptive and cultural notes and tabulated data on 39 varieties of strawberries grown on the station farm. The plants were mulched the previous fall with straw, which was not removed until the middle of April, thus sheltering the plants through the winter and until after the spring frosts. Uncovered plants bloomed in March and were killed by a severe freeze the latter part of the month. The rainfall was less than normal and the mean temperature of the spring was low, resulting in a reduced crop of berries, only about one third the average yield being matured. Three tables are given, one showing the comparative yield of the varieties as determined from 6 plants of each sort, another giving the dates of bloom and fruit production and quality, and the third giving data for the 10 most productive varieties. Brandywine, Cyclone, Longfield, and Tennessee, comparatively new varieties, are considered among the best. A list of 134 varieties, tested up to date at the station, is given.

The grafting of grapes, E. G. LODEMAN (*New York Cornell Sta. Bul. 77, pp. 459–476, figs. 16*).

Synopsis.—Illustrated directions for the various methods of grafting grapes, with remarks on the physiology of grafting.

Introduction (pp. 459–464).—The structure of the grape stem is described and figured and the physiology of the combination of the stock and scion is given. It is urged that the scion be dormant or at least less active than the stock. Grafting is recommended to be performed either in the fall after the flow of sap has ceased, early in the spring before the flow has begun, or in late spring when the first activity of the sap has diminished. Early spring is considered as perhaps the most suitable time.

Methods of grafting (pp. 464–475).—Directions are given for making cleft grafts, crown grafts by inlaying, cutting grafts, modified tongue grafts, side grafts on stocks, and on root cuttings. The directions are given in detail and the implements and processes are fully illustrated. Cleft grafts are mentioned as being made by either completely or only partially severing the stock. Grape grafting is believed to be followed by better results if the scions are inserted below the surface of the ground. Cleft grafting and side grafting are considered the most suitable and satisfactory methods. Cuttings are best grafted by tongue graft.

A concise summary is given embodying the important points made in the bulletin.

Fruits, R. L. WATTS (*Tennessee Sta. Bul., vol. VII, No. 2, pp. 143–156*).

Synopsis.—Cultural and varietal notes on grapes, strawberries, raspberries, blackberries, pears, apples, and peaches.

Grapes (pp. 143-150).—Ninety varieties, comprising 391 vines, are being grown in the station vineyard, most of which fruited the past season. Brief descriptive notes are given on 31 varieties. The diseases, black rot and brown rot, attacking the vines and leaves, are briefly described, and directions for treatment by spraying with copper sulphate, Bordeaux mixture, or ammoniacal carbonate of copper are given; formulas for preparing these fungicides are included. The culture given the vineyard is briefly mentioned.

Strawberries (p. 150).—Brief notes on several varieties, the yield being greatly diminished by spring frost. Crescent, Haverland, Jessie, Windsor Chief, and Bubach were most productive.

Raspberries (pp. 150, 151).—Brief descriptive and comparative notes on the following varieties: Turner, Reliance, Golden Queen, Cuthbert, and Shaffer Colossal. The black caps were injured by frost and bore very scantily.

Blackberries (p. 151).—A list of 11 varieties, arranged in order of productiveness, Early Cluster and Kittatinny giving much the heaviest yields.

Pears (p. 151).—Notes on the culture of the pear orchard belonging to the station, the varieties Bartlett, Kieffer, and Beurre Giffard being planted.

Apples (pp. 152, 153).—Notes on work being done in the preparation of a catalogue of Tennessee apples. The fruit and foliage are photographed, and careful notes are made. In the case of promising seedlings, grafts are made upon bearing stocks in the station orchard. Coöperative work on the apples of the State is being done by numerous correspondents.

Peaches (pp. 153–155).—Notes on investigations in regard to peach growing in Tennessee, with brief recommendations for satisfactory culture. Information from peach growers of the State is requested in regard to various seedlings, soils, diseases, and culture.

A list of the donations to the horticultural division of the station in 1894 is appended.

Report of the horticulturist, W. M. MUNSON (*Maine Sta. Rpt. 1893, pp. 101–144, figs. 2*).

Synopsis.—This contains reports on the work of the year, comprising notes on cabbages, cauliflowers, tomatoes, eggplants, spraying experiments, and a catalogue of Maine fruits.

Cabbages (pp. 101–105).—Experiments were made to determine the influence of transplanting young plants, the effect of trimming at the time of setting in the field, and the result of holding plants in check. Plants twice handled in pots gave results slightly superior to those obtained from like plants handled the same number of times in boxes. In no case did the plants from boxes produce heads equal to the best of those from pots. The results obtained by reducing the amount of foliage at the time of setting in the field were almost negative. The results of 2 seasons' experiments indicated that little advantage is to be derived from the practice. Holding plants in check on account of severe weather by closely heading them back was found to render them earlier and slightly larger than others left untreated as checks. It is advised to prune the foliage of the plants likely to become drawn and crowded before planting out. The data for the experiments are tabulated.

Cauliflowers (pp. 105–111).—Chiefly a reprint of Bulletin 10 of the station (E. S. R., 6, p. 51). In addition are given tabulated data for the handling of cauliflowers in pots *vs.* boxes, the effect of trimming cauliflowers at the time of planting, and a comparison of 30 varieties of cauliflowers. An increased percentage of marketable heads, amounting in some varieties to 20 per cent, was the result of handling the young plants in pots. In the experiment of trimming plants the per cent of heads formed was greater for plants not trimmed, though there was no difference in earliness or size of the heads. Early varieties produced more marketable heads than did the late, and where the heads produced were very large the percentage of plants heading was correspondingly small.

Tomatoes (pp. 112–118).—Chiefly a reprint of Bulletin 9 of the station (E. S. R., 6, p. 51), with the addition of tabulated data on the effect of early setting, value of pot culture, individual variation, and a comparison of first and second generations of crosses. Early setting is recommended, though the advantage gained in earliness and productiveness of fruit was but slight. Plants handled 3 times in pots showed a marked increase in productiveness over those transplanted a like number of times in boxes. The individual variation within varieties was found to be often so much as to obscure the effects of different methods of culture. A cross between the Ignotum and Peach varieties showed a marked falling off in the second generation over the advantage indicated by the first, although this may have been due to greater care given the first generation.

Eggplants (pp. 118–121).—Notes and tabulated data on early *vs.* late setting, deep *vs.* shallow cultivation, frequent cultivation, and the effects of root pruning. Early setting, when the plants escaped injury by frost, gave a large advance in the percentage of plants bearing marketable fruits, in the case of the Black Pekin variety amounting to 35 per cent. Deep cultivation with a horse hoe gave much better results than shallow hand work. Experiments with frequent cultivation were obscured by the failure of the varieties employed. Root pruning gave contradictory results.

Potatoes (pp. 121–124).—A reprint of Bulletin 12 of the station (E. S. R., 6, p. 632).

Spraying experiments (pp. 124–128).—A reprint of Bulletin 8 of the station (E. S. R., 5, p. 1077). In addition is given a table showing the details of an experiment in spraying to prevent apple scab, merely the results of which are given in the bulletin.

Catalogue of Maine fruits (pp. 129–144).—Tabulated data for 110 varieties of apples, 9 of crab apples, 14 of blackberries, 2 of dewberries, 20 of cherries, 10 of currants, 5 of gooseberries, 14 of grapes, 3 of quinces, 35 of pears, 29 of plums, 17 of raspberries, and 25 of strawberries. In addition, lists are given of the varieties believed to be profitable for the northern and southern counties of the State, and apples for home use and for market, with several varieties found unsatisfactory in the northern counties.

Small fruits in 1893, G. C. BUTZ (*Pennsylvania Sta. Rpt. 1893, pp. 118–126*).—Cultural and descriptive notes and tabulated data for 34 varieties of strawberries, 20 of raspberries, 10 of blackberries, 9 of currants, and 6 of gooseberries. Greenville and Shuster Gem gave the heaviest yield of strawberries, and the total yield from mats was 10 per cent better than that from hills. Of raspberries Caroline, Brinkle Orange, Marlboro, Cuthbert, Rancocas, Shaffer Colossal, Souhegan, Mammoth Cluster, and Ohio are recommended as the best of the different colors they represent. Early Harvest, Eldorado, Jewett, and Snyder proved the best blackberries; and the Cherry, Red Dutch, and White Grape were the most productive currants. The Smith gooseberry yielded the most fruit, followed closely by the Houghton.

Manuring of fruit trees, LIERKE (*Mitt. deut. landw. Ges., 1893-'94, No. 12, pp. 167-171; abs. in Centbl. agr. Chem., 23 (1894), No. 10, pp. 702, 703*).—Notes on fertilizer experiments begun in 1891 under the direction of the Dresden Agricultural Experiment Station, in orchards on the manor of Rottwerndorf. Twenty-three plats were employed, being treated with various animal manures and different combinations and quantities of chemical fertilizers. At this time the nitrogen and potash fertilizers seem to be producing too vigorous a growth of foliage and shoots, to the detriment of the fruit, but the results are not yet established or conclusive, and the experiments are to be further pursued.

On the manuring of fruit and garden crops and the relation of live stock to fertility, J. W. FIELDS (*Pennsylvania Sta. Rpt. 1893, pp. 61-65*).—A general, popular paper on intelligent horticultural fertilizing. Tables are given showing the fertilizing content of the more common orchard and small fruits and garden vegetables. In growing these crops the return of nitrogen to the soil is urged to be as essential as the return of potash and phosphoric acid, an amount approximating that removed, depending on the nature of the soil and its natural fertility, being returned. A formula is given for a general fertilizer. The value of manure from farm animals in returning to the soil the fertilizing constituents taken from it by the crops is briefly mentioned, and a table is given showing the number of pounds of fertilizing ingredients in a ton of various farm products, and some commercial feeding stuffs with their fertilizing value per ton.

Tests of vegetables in 1893, G. C. BUTTS and G. BALDWIN (*Pennsylvania Sta. Rpt. 1893, pp. 126-142*). Descriptive notes and tabulated data on 6 varieties of bush Lima beans, 6 of bush beans, 6 of pole beans, 6 of beets, 1 of celery, 7 of early cabbage, 4 of late cabbage, 11 of corn, 9 of cucumbers, 11 of lettuce, 7 of onions, 16 of peas, 10 of squash, and 25 of tomatoes. A list of donations to the horticultural division of the station during 1893 is appended.

Glasshouses, their construction and heating, H. W. GIBBONS (*Amer. Florist, 10 (1895), No. 350, pp. 377, 378*).—Detailed architectural directions for building plant houses.

Horse-radish, G. M. STRATTON (*Amer. Gard., 16 (1895), No. 32, p. 54*).—Detailed cultural notes.

The cultivation of the melon, W. PALMER (*Jour. Hort., 1895, No. 2419, pp. 118, 119, fig. 1*).—A popular article on growing melons in hothouses in England, giving full directions for producing prize fruit. The illustration is from a photograph of a plant of the Triumph variety, loaded down with fruit, and supported on wires.

Edible and poisonous mushrooms, C. COOKE (*London: 1894, pp. 126, figs. 18*).—Reviewed in *Rev. Scientif., 10 (1895), No. 3, p. 84.*

Edible fungi in Surrey, C. A. BRIGGS (*Sci. Gos., n. ser., 1 (1895), No. 11, pp. 251, 252*).—The author mentions the following species as edible: *Agaricus campestris, A. arvensis, A. gambosus, A. rubescens, A. vaginatus, A. prunulus orcella, A. personatus, A. nudus, Boletus lutens, Lycoperdon plumbeum, L. bovista, Morchella esculenta, Sparassis crispa,* and *Fistulina hepatica,* all of which he says are easily recognized and very palatable.

Rhubarb (*Amer. Gard., 16 (1895), No. 32, p. 46, fig. 1*).—Brief notes on planting, fertilizing, and marketing.

Sago cultivation in Borneo (*Kew Misc. Bul. 96, pp. 414–417*).

The apricot, B. M. LELONG (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 29–55, figs. 12*).—An elaborate paper treating of the origin of the apricot, its propagation, soil, planting, pruning, thinning, fruit picking, grading, cutting for drying, sulphuring, drying, sweating, packing the dried fruit, and illustrated, descriptive, and comparative notes on 35 varieties. Notes from various growers in the State bearing on different points are included. California is believed to be peculiarly adapted to the apricot. Special stress is laid on the preparation of the dried fruit. Illustrations are given of apricot trees and orchards, showing the manner of growth and the effect of proper pruning.

The cherry, B. M. LELONG (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 55–63, pls. 19, figs. 2*).—Notes on the growing of cherries in California, with remarks on the soil, propagation, planting, pruning, cultivation, picking and packing, diseases and pests, and illustrations of 26 leading varieties, many of which are figured for the first time. The pits of 31 varieties are figured to show the different types of form for classification purposes. The rich valley lands of the State are the principal cherry producing sections, and a number of valuable varieties have been originated in California. Notes from several cherry growers of the State are incorporated.

Fig culture and fig packing, D. SHERMAN (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 234–236*).—Notes on the cultivation, gathering, processing, and packing of figs, the different steps of the preparation for market being given in detail.

Curing the white Adriatic fig, G. A. RAYMOND (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 270–272*).—A detailed account of the method of curing this variety of fig employed by the author.

The pomelo, B. M. LELONG (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 63–65*).—Brief descriptive remarks on *Citrus pomelanus* and its value as a medicinal fruit. Several newspaper articles are included. The cultivation of the pomelo in California is urged.

Prune culture from a commercial standpoint, J. E. GORDON (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 204–213*).—A general paper on the growing of prunes, embodying earnest recommendations as to the best methods of cultivating, picking, drying, and marketing.

The mulberry, G. ABBEY (*Jour. Hort., 1895, No. 2419, pp. 112, 113*).—A popular paper on the cultivation and uses of the tree, leaves, and fruit, including an historical sketch.

The buffalo berry, L. C. CORBETT (*Amer. Gard., 16 (1895), No. 32, p. 45, figs. 2*).—An illustrated article pointing out the distinction between the staminate and pistillate forms of *Shepherdia argentea.* The paper was read at the last meeting of the Association of American Agricultural Colleges and Experiment Stations.

Dewberries are worth cultivating, I. N. STONE (*Amer. Gard., 16 (1895), No. 32, p. 45*).—Brief notes on the growing of dewberries, the variety Bartel being preferred to Lucretia, as it is more prolific and nearly thornless.

Rubus australis, W. J. BEAN (*The Garden, 47 (1895), No. 1212, p. 100, fig. 1*).—Descriptive notes on this New Zealand bramble, which is advised as an addition to cool conservatories.

Cross fertilization of grapes, S. B. GREEN (*Minnesota Sta. Rpt. 1893, pp. 229–231, fig. 1*).—A reprint from Bulletin 32 of the station (E. S. R. 6, p. 46).

Pot grapevines vs. planted canes, G. WYTHES (*Gard. Chron., 17 (1895), ser. 3, p. 176*).

The importance of hybrids in replanting vineyards, A. MILLARDET (*Compt. Rend., 119 (1894), No. 26, pp. 1176–1180*).

Three years' observations on the action of plaster in viticulture, G. BATTANCHON (*Prog. Agr. et Vit.; L'Engrais, 10 (1895), No. 5, pp. 114, 115*).

Fruits and soils of the arid region, E. W. HILGARD (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 303–312*).—A paper embodying the results of over a thousand analyses of soils from arid regions. Compared with analyses of humid soils, the arid lands possess about 3 times as much potash and 12 to 14 times as much lime, while there is no material difference in phosphoric acid. Analyses of fruits indicate that those grown in arid regions were of better quality, particularly possessing more sugar. Attention is drawn to the fact that the earliest civilization originated in localities with but scanty rainfall, such as Egypt and India. Some of the analyses of soils of the United States are tabulated.

Fruits, notes on varieties, S. B. GREEN (*Minnesota Sta. Rpt. 1893, pp. 239–247*).—A reprint from Bulletin 32 of the station (E. S. R. 6, p. 55).

Fruit forcing (*Jour. Hort., 1895, No. 2419, pp. 124, 125*).—Brief directions for forcing pineapples, figs, cherries, strawberries, cucumbers, and melons in hothouses.

Thinning fruit (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 341–343*).—A general discussion of the subject and the extent to which it should be pursued in different kinds of fruits.

Orchard fertilization, A. S. CHAPMAN (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 313, 314*).—Notes on experiments in using different fertilizers on a sandy soil for the raising of citrus fruits and grapes. Potash fertilizers gave the best results.

Irrigation for the development of fruit, H. A. BRAINARD (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 216–220*).—A discussion of the value of irrigation in fruit raising, and recommendations for its adoption and extension.

Fruit growing in the Santa Maria Valley, O. W. MAULSBY (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 221–223*).—A general discussion of the subject, with a consideration of the soil and climate. Apricots, prunes, English walnuts, peaches, almonds, and cherries are grown in the order given.

Notes on fruit growing at Mildura, A. H. BENSON (*Agl. Gaz. N. S. W., 5 (1894), No. 11, pp. 765–772*).—General notes on the growing of citrus and other fruits in this part of Australia, with remarks on the varieties found best, and on the climate, soil, irrigation, cultivation, and drying of the crops.

Suggestions on horticultural quarantine, A. CRAW (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 290–294*).—General remarks on the subject, laws bearing on it, and its enforcement.

California almonds (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 417–419, pls. 4, fig. 1*).—Descriptive notes on 13 varieties of almonds which are divided into 4 grades, hard shell, soft shell, extra soft shell, and paper shell. A table is given showing the weight of the kernel and shell in a pound of almonds of 12 different varieties, and the relative value of leading California varieties compared with others.

The pistachio (Pistacia vera), G. HEUZÉ (*Jour. Agr. Prat., 59 (1895), No. 4, pp. 143, 144*).

Pecan culture in the arid regions, F. A. SWINDEN (*Irrigation Age, 8 (1895), No. 2, pp. 54, 55, figs. 5*).

Some desirable ornamental trees, shrubs, and plants for planting in Ontario, W. E. SAUNDERS (*Ontario Fruit Growers' Assn. Rpt. 1893, pp. 90–97*).—General remarks on these subjects, with comparative cultural notes on several species of pine, spruces, retinosporas, maples, horse-chestnuts, alders, birches, yellowwood, walnuts, maidenhair tree, oak, false indigo, flowering almond, Siberian pea, dogwoods, mock orange, spiræas, and other trees and shrubs.

FORESTRY.

Five years' experience in planting forest trees, W. A. BUCKHOUT (*Pennsylvania Sta. Rpt. 1893, pp. 153–155*).—Experiments have been in progress to test tree and seed planting at the college grounds and on a small area of wild land. The details of preparation and planting were given in the report of the station for 1888 (E. S. Bul. 2, pt. 2, p. 136). The results have not been wholly satisfactory. The mountain plat proved not well adapted to the purpose, as the undershrubs crowded out that which was planted. The chestnut trees failed entirely in the mountain plat and grew very poorly at the college. A reason for this is that the ground was too loose and permitted the deep taproot to dry out before the lateral roots were developed. The white pine trees at the college made the best growth, averaging 4 to 5 ft. in height. The mountain planting of the same kind of trees gave smaller, weak trees, which are not well established. The principal injury to these trees was done by the pine weevil (*Pissodes strobi*) and the woolly pine louse (*Schizoneura pinicola*).

The author concludes that considering the time, expense, and risk involved, artificial forest planting can not be recommended, at least in the way pursued in the experiment, and that natural methods of reforesting, supplemented by some seed sowing, thinning, and planting, will suffice for the present and the near future.

Experience with evergreens in Pennsylvania, G. C. BUTZ (*Pennsylvania Sta. Rpt. 1893, pp. 142–149, pl. 1*).—A reprint from Bulletin 23 of the station (E. S. R., 5, p. 54).

The long leaf pine and its struggle for existence, W. W. ASHE (*Jour. Elisha Mitchell Sci. Soc., 11 (1894), No. 1, pp. 1–16*).

The planting of beech trees, P. HAUGUEL (*Rev. Hort., 66 (1894), No. 24, pp. 584, 585*).—General notes on this point.

The black walnut in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), p. 12*).

The green ash in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), p. 32*).

The white elm in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), p. 53*).—This tree is recommended as a forest tree for the West on account of its resistant powers and rapid growth.

The New South Wales blue gum, J. H. MAIDEN (*Agl. Gaz. N. S. W., 5 (1894), No. 11, pp. 743–747, pl. 1*).—Illustrated and descriptive and economic notes on *Eucalyptus saligna.*

Notes on the tree flora of Chiricahua Mountains, I, J. W. TOUMEY (*Garden and Forest, 8 (1895), pp. 12, 13*).—An account of a botanical excursion through northern Mexico and southern Arizona.

A descriptive list of the trees of Java, S. H. KOORDERS (*Mededeelingen 'SLands Plantentuin, 1894, No. 12, pp. 175*).

Water and forestry and agricultural production, L. GRANDEAU (*Jour. Agr. Prat., 59 (1895), No. 2, pp. 50–52*).—A brief résumé of the work of Henry Schübler, Schlösing, and Wollny.

Forest conservation, A. KINNEY (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 326–328*).—A general popular article urging the importance of the preservation of forests from destruction and their influence on rainfall. Federal control of forest lands is advocated.

Ringbarking in western New South Wales, T. KIDSTON (*Agl. Gaz. N. S. W., 5 (1894), No. 11, pp. 762–764*).—Notes on removing forests by the employment of this method of deadening the trees. The author does not believe that the destruction of forests lessens rainfall.

Forest fires, W. A. BUCKHOUT (*Pennsylvania Sta. Rpt. 1893, pp. 155–159, fig. 1*).—A reprint from Bulletin 23 of the station (E. S. R., 5, p. 54).

Forest fires in North America, B. E. FERNOW (*Ztschr. Forst. und Jagdw., 17 (1895), No. 1, pp. 31–35*).

Forest fires, causes and preventions (*Forest Leaves, 5 (1895), No. 1, p. 15*).—An abstract from the *Boston Commercial Bulletin*, giving statistics on the subjects, number of fires, acres burned, loss, etc.

Fire and flood, J. T. ROTHROCK (*Forest Leaves, 5 (1895), No. 1, pp. 8, 9, pls. 2*).—An article dealing with the destruction of forests in Pennsylvania and discussing the injury to the soil and property. The plates are from photographs, showing the tracks of forest fires and freshets.

Forest destruction by means of Gryllus campestris and Tettix subulata, ALTUM (*Ztschr. Forst. und Jagdw., 17 (1895), No. 1, pp. 12–17*).

Thirteenth Annual Meeting of the American Forestry Association, B. E. FERNOW (*Forest Leaves, 5 (1895) No. 1, pp. 10, 11*).—A general account of the proceedings of the meeting, with the resolutions adopted favoring forest legislation.

California Forestry Experiment Stations, II, C. H. SHINN (*Garden and Forest, 8 (1895), pp. 62, 63*).—A description of the Santa Monica forestry station.

Forestry in Natal (*Kew Misc. Bul. 97, pp. 1–5*).

SEEDS—WEEDS.

Seed testing, its uses and methods, G. MCCARTHY (*North Carolina Sta. Bul. 108, pp. 347–415, figs. 44*).—The author has brought together from various sources a fund of information relating to the subject of seed testing. The necessity and uses of seed testing are pointed out and a brief review of what has been done in the United States is given, together with a statement of the seed control system of Europe and the methods by which it is conducted. Numerous tables are given showing the viability, genuineness, and value of different kinds of seed. A chapter on the physiology of the seed gives briefly the structure, germination, composition, effect of temperature, light, electricity, and chemicals on germination, specific gravity and volume weight of seed, and the life period of the embryo. In the chapter on practical seed testing are given compiled tables showing the viability, purity, and germination of a large list of forage plants, field and garden crops, and flower seed; the impurities and adulterations of seed and the limits of error in testing, and descriptions of apparatus and methods employed in seed testing. The author has drawn on the various station publications of this country as well as the leading seed control stations of Europe for the facts set forth in this bulletin.

New Mexico weeds, I, E. O. WOOTON (*New Mexico Sta. Bul. 13, pp. 36, figs. 15*).—This bulletin is the first of a series to be devoted to the subject of the weeds of New Mexico, and gives some general information on weed dissemination and repression. The list enumerated embraces 18 species, as follows, the most of which are figured: Nigger

weed (*Sphæralcea angustifolia*), *Sida hederacea*, *Gaura parviflora*, blue weed (*Helianthus ciliaris*), sunflower (*H. annuus*), cocklebur (*Xanthium canadense*), spiny aster (*Aster spinosus*), *Franseria hookeriana*, *Aster canescens*, morning glory (*Ipomœa mexicana* and *I. purpurea*), horse nettle (*Solanum elæagnifolium*), common pigweed or rough amaranth (*Amarantus retroflexus*), rough amaranth (*A. chlorostachys*), low amaranth (*A. blitoides*), lamb's quarter or goosefoot (*Chenopodium album*), sand bur or bur grass (*Cenchrus tribuloides*), *Chloris alba*, and loco weed (*Astragalus mollissimus*).

Western plantain, F. L. HARVEY (*Maine Sta. Rpt. 1893, pp. 157, 158, fig. 1*).—A description and illustrations of *Plantago patagonica aristata* are given, with a report of its appearance in an oat field during the year. The author calls attention to this weed being an annual, and suggests its easy eradication by preventing its setting seed.

The Russian thistle, L. H. DEWEY (*U. S. Dept. Agr., Division of Botany Circular 3, pp. 8, figs 3*).—Popular information is given on the nature, distribution, and remedies for this weed. It is now known to be present in 18 States, and also in 3 of the Canadian provinces.

The sachalin knot weed, L. H. PAMMEL (*Garden and Forest, 8 (1895), p. 67*).—The author refers to 12 years' experience with this plant, and says it spreads very rapidly by means of its rhizomes, and land set in it may have to be given up to it as in the case of the Johnson grass in the South.

DISEASES OF PLANTS.

Some grape troubles of western New York, E. G. LODEMAN (*New York Cornell Sta. Bul. 76, pp. 413–454, figs. 6*).

Synopsis.—The author describes and offers suggestions for the repression of shelling or rattling (a disease of rather uncertain origin), powdery mildew, anthracnose, black rot, brown rot or gray rot, and ripe rot. Brief notes on spraying apparatus and formulas for 3 of the best fungicides are given.

Shelling or rattling (pp. 413–440).—This disease, which although not new was more or less troublesome throughout the grape-growing portions of the State, is characterized by the author as follows:

"The shelling of grapes takes place in the following manner. As the season of ripening approaches, certain berries of the affected clusters fall to the ground on account of the inability of the main fibers and other connecting tissue of the fruit-stems to sustain their weight. . . . The end of the stem is even, as if cut with a knife.

"The portions of the cluster first affected are, so far as my observations go, invariably either the lower extremity of the cluster as it hangs from the cane, or in the case of heavily shouldered clusters, the outer extremity of the stem forming the shoulder. The shelling may begin at both points at about the same time, but it generally makes its appearance first at the lower end of the bunch. Sometimes only one or two berries may fall, but in other cases the drying and shriveling of the stem gradually extends upward, the affected portion being plainly marked by the absence of the berries. It often occurs that not a berry remains hanging upon the bunch. In such cases the ground below the bearing portions of the vine is literally covered with the fallen fruit. . . .

"Some clusters upon a vine seem to be more free from shelling than others upon the same plant. This seems to be due in many cases to its location upon the cane, but there are so many exceptions that no definite rule can be laid down. In general, however, it may be said that of the clusters found upon a certain cane the one which is situated farthest from the main stem of the plant is most seriously affected. . . .

"Another peculiarity which may sometimes be seen, although cases of it are very rare, is the shelling of berries upon only one portion of the vine, as, for instance, those borne upon the canes which spring from an arm, the difficulty thus affecting only one half of the plant. . . .

"It very commonly occurs that plants in certain portions of a vineyard shell, while the large majority of them do not. The line is sometimes so sharply drawn that the affected plant may be entirely surrounded by healthy vines; and it is not uncommon to find a healthy vine in the midst of those which shell. Occasionally the plants in a row are quite different as regards the amount of fruit which is lost, some retaining all, while others lose fully 75 per cent. Such vineyards, however, do not represent the large majority. In these, the shelling is more or less uniform throughout the vineyard, and only in exceptional cases does the loss reach 50 per cent of the crop. The total loss will probably not exceed 5 per cent of the entire yield this year.

"The taste of shelled grapes differs decidedly from that of those remaining upon the upper portion of affected clusters, and still more from that of berries which are borne upon vines in which no shelling takes place. This difference is very noticeable in Concords. Grapes of this variety, when grown under favorable conditions, are sweet and very agreeable to the taste, on account of a flavor which is peculiar to the variety. Shelled grapes are extremely insipid, and are unpalatable, not only from a want of taste but also from a certain disagreeable flavor which, though seldom strong, is still perceptible. Berries which remain upon shelly vines lack flavor, but otherwise they do not appear to possess any particularly disagreeable qualities."

Vines which have shelly grapes are said to be nearly always affected by diseased foliage. This condition usually appearing in July or August, causes the death of the leaf tissues. The leaves on the extremities of the shoots show a yellow coloration more or less following their periphery. Soon the yellow portion turns brown, causing the leaf to curl. In severe cases the brown foliage becomes conspicuous. The shelling is not always accompanied by a decided discoloration, but the two are usually associated. A dark discoloration is often found between the principal veins and is attributed to the same cause as that causing the death of the edges. In some of its aspects this disease resembles apoplexy and rougeot, common in parts of Europe, but the author doubts their identity. In 1890 D. G. Fairchild, of the Division of Vegetable Pathology of this Department, investigated and reported on[1] a disease of grapes probably the same as here described.

The ascribed causes of the shelling are grouped by the author under 4 heads—(1) injuries due to parasites, (2) improper conditions of the vine, (3) conditions of the soil, and (4) conditions of the atmosphere. In considering the various causes the author thinks that insects do not cause the disease, but that fungi may aggravate it, and that the dying of the leaves is a manifestation of the disease. The conditions of the vine, causing the stems to shrivel and the fruit to ripen prematurely probably cause this trouble. Premature ripening of the wood and overbearing weaken the vine and may to some extent cause shelling. Too much wood, due to improper proportion of the elements required for the plant, especially a superabundance of nitrogen, seems to increase the amount of shelling. The kind of soil, not considering the food supply it contains, appears to have no effect, but too much cultivation, by liberating the nitrogenous compounds, aggravates the trouble. Excessive drought and rains influence the amount of disease to some extent. A weak root system has the same effect as overbearing. The disease has been checked by applications of barnyard manure. A lack of phosphoric acid has no effect. In most cases the plants seem to be suffering from a lack of potash, and applications of that fertilizer have been followed by a decrease or disappearance of the disease. Excessive heat and warm winds, by inducing rapid growth, increase shelling, while cool winds or weather checks it. From reports received from quite a number of vineyardists the application of potash to the vines checked shelling, and based on only one year's experience this treatment is recommended.

---

[1] Jour. Mycol., vol. 6, p. 96 (E. S. R., 2, p. 455).

Powdery mildew (p. 441).—This disease prevailed to a considerable extent during 1894 in the Chautauqua vineyards. The application of Bordeaux mixture or ammoniacal copper carbonate is recommended as a treatment.

Anthracnose (pp. 442, 443).—This disease has been very severe on Moore Diamond and Brighton varieties, and it is recommended that growers make a trial of the acid sulphate of iron solution, the formula for which is iron sulphate 110 lbs., sulphuric acid 1 qt., water 26 gal.

Black rot, brown or gray rot, and ripe rot (pp. 444–448).—These diseases were somewhat prevalent in certain regions, and the usual fungicides are recommended. The reported failure of some vineyardists to prevent these diseases was due, the author thinks, to too thick foliage and improper application of fungicides. In some vineyards the vines suffered from drought. For these shallow and frequent cultivation is advised.

Spraying apparatus (p. 450).—Different forms of apparatus are described. The knapsack machine is considered the most effective. Hand pumps, the author says, allow of more rapid but less efficient work, while power sprayers are, under favorable circumstances, the most desirable for use in vineyards.

Formulas for fungicides (pp. 450, 451).—Formulas are given, together with directions for preparation for Bordeaux mixture, ammoniacal copper carbonate solution, and acid iron sulphate solution.

Report of botanist, F. L. HARVEY (*Maine Sta. Rpt. 1893, pp. 145, 146, 150, 152–158, figs. 5*).

Synopsis.—The author reports briefly on the fungus diseases occuring during the year, and at greater length on bean anthracnose, tomato anthracnose, potato and beet scab, and western plantain. In addition to the diseases reported on at some length, the following have been more or less prevalent in parts of the State: Pear leaf blight, clover rust, and strawberry septoria.

Bean anthracnose (pp. 152, 153).—This disease, due to the presence of *Colletotrichum lindemuthianum*, has been quite common, attacking both bush and pole varieties of beans, but being most destructive to the white-podded varieties. The disease is described and the following precautions are given for preventing the spread of the disease:

"Select good seed, rejecting all beans that seem at all unsound.

"Should the disease appear in the young beans carefully destroy all affected seedlings.

"If convenient spray early with Bordeaux mixture and repeat the application, if needed, before the pods form.

"Do not plant on ground that has borne an infected crop the past season.

"Plant on a dry soil in hills or in rows far enough apart to admit air freely. Hoe when the ground and foliage are dry."

Tomato anthracnose (pp. 154, 155).—This disease, which caused considerable destruction in the station garden, was described in the Annual Report of the Delaware Station for 1891, p. 60 (E. S. R., 5, p. 591), as *Colletotrichum lycopersici*, but is here called *C. phomoides*. The disease appears on the ripe or nearly ripe fruit, producing discolored, sunken spots with black centers. Successful inoculations have been made, but placing spores on the unbroken epidermis of the tomato failed to produce the disease. A spray of potassium sulphid solution, 7 oz. in 22 gal. of water, together with the destruction of all diseased plants and rotation of crops, are the remedies recommended.

Potato and beet scab (p. 156).—Compiled notes are given showing the identity of these diseases, and the corrosive sublimate treatment is recommended for their prevention.

Miscellaneous botanical work, W. A. BUCKHOUT (*Pennsylvania Sta. Rpt. 1893, pp. 150–153, pl. 1*).—*Experiments for preventing potato diseases* (pp. 150–152).—Experiments were conducted with Bordeaux mixture for the prevention of potato rot with negative results, no blight or rot appearing on any of the plants. The sprayed plants showed a more vigorous appearance of their tops than the unsprayed. The effect of early planting was tried. Plats were planted April 28 and May 7. There was a marked difference in the appearance of the plants until August, when there was little or no appreciable difference. Owing to the hot dry weather of midsummer there was no disease present. When harvested the early plat yielded 1,100 lbs. to 882 from the later planted one. These experiments were to have been repeated in 1893 to see if the same results would be secured, but were overlooked. As the rot does not usually appear until late in July the experiment of early planting is to be investigated further.

Spraying grapes (p. 152).—In 1891 10 varieties of grapes not sprayed were observed, and downy mildew was conspicuous on the Delaware, Brighton, Duchess, Lindley, and Salem varieties. In 1892 the growth of these varieties started very slowly, the Brighton and Duchess vines being nearly dead. Three applications of Bordeaux mixture were given the vines with negative results, there being no mildew that year. In

1893 the experiments were repeated with the same results, and the difference between the sprayed and unsprayed portions of the rows was indistinguishable. A Niagara vine within the sprayed portion showed some black rot, all others being free from the disease. Unsprayed Concord vines produced a full crop free from disease each year.

Leaf spot of beet (pp. 152, 153).—This disease, due to *Cercospora beticola*, was very noticeable. The author thinks spraying would probably prevent it, also that the same result would be secured by a rotation of crops, together with a thorough destruction by fire of all infected leaves upon the ground where grown in such a way as to burn the surface of the ground slightly, destroying the weeds and accumulated rubbish. The injury to the roots is said to be in a direct ratio to the amount of spotting on the leaves.

Wheat scab (p. 153).—This disease is reported as having been more or less abundant, but no experiments were conducted for its repression.

An infection experiment with club root of turnips (finger and toe disease), W. SOMERVILLE (*Jour. Roy. Agl. Soc. England, ser. 3, 5 (1894), No. 20, pp. 808–811, fig. 1*).—The author reports on field experiments with lime for the prevention of club root (*Plasmodiophora brassicæ*) of turnips. The turnips were grown in soil that was not infected in small duplicate plats. The infection was secured by adding to each plat 20 lbs. of soil taken from a field known to be badly infested. Finely ground fresh lime was added to the inoculation soil in ⅛, ¼, 1, and 5 per cent amounts. The lime was ground to such a degree that 90 per cent passed through a number 100 sieve. The yields given were as follows:

Soil inoculation experiment with club root.

Plat.	Infected soil.	Per cent of lime to infected soil.	Number of roots.	Number of diseased roots.	Number of sound roots.	Calculated yield per acre.
	Pounds.					*Bushels.*
1	0	0	42	0	42	354
2	20	0	31	30	1	314
3	20	⅛	38	35	3	421
4	20	¼	33	28	5	374
5	20	1	36	26	10	474
6	20	5	40	4	36	630

The above experiments show the infectious nature of the disease and that it may be greatly reduced by the application of lime to the soil. The author considers an application of about 700 lbs. of finely ground lime equal to an application of 5 tons per acre applied in the usual way. The relative cost and the comparative value of quick and slaked lime are to be subjects for further investigation.

Attacks of Phoma on growing roots, E. ROSTRUP (*Ztschr. Pflanzenkrank., 4 (1894), No. 6, pp. 322, 323*).—The author describes 2 species of *Phoma* that attack root crops of Denmark. The first attacks the kohl rabi and to it the name *Phoma napobrassicæ* has been given. The other, which has been described by the author as *P. sphærosperma*, attacks beet roots. As this name had been preoccupied, the name now given it is *Phoma betæ*. It is thought by the author that this *Phoma* is genetically related to *Sporidesmium putrefaciens*.

Rust in wheat (*Proc. Rust in Wheat Conf., Brisbane, Queensland, 1894, March, pp. 77*).—Progress reports were given by various committees, and the consensus of opinion seems to be that more attention should be paid to the harder wheats, especially those having narrow leaf blades and which are to a considerable degree glaucous, as the most promising rust resistant varieties. Lists are given of what are considered the more resistant varieties, but they vary in different parts of the country represented. Numerous experiments were reported of the ineffectual use of fungicides on the seed before sown. The report concludes with illustrated descriptions of 45 of the more prominent varieties of wheat.

Treatment for sooty mold of the orange, H. J. WEBBER (*U. S. Dept. Agr., Division of Vegetable Pathology Circular 15, pp. 4*).—The sooty mold of the orange, considered by the author as probably due to *Meliola* spp., produces a very marked effect on the tree and fruit. The leaves and fruit are covered by a black soot-like membrane which greatly hinders the processes of assimilation, and the fruit when ripe is small, insipid, and of a very inferior character. In severe cases the trees fail to produce any fruit.

Experiments show that resin washes are very effective remedies in preventing this disease. The formula recommended is resin 20 lbs., caustic soda 4½ lbs., crude fish oil 3 pt., water to make 15 gal. Place the materials in a large kettle with 13 gal. of water and boil until the resin is dissolved, then add water to make 15 gal. This is a stock solution. When used it must be diluted to 150 gal., and will cost about 45 cts. for such an amount. When too strong the wash will burn the fruit, but in the strength here given no injury will follow. The author states that the disease is only serious in its attack when accompanying the white fly or mealy wing, *Aleyrodes citri*. In badly affected groves 3 periods of application must be observed. Beginning the middle of January, 3 applications should be given at intervals of 2 weeks. In May and June is a second period when the trees should be sprayed, and the third period is in August and September. The spray is easily washed off by rain and should be repeated when a rainfall occurs soon after spraying. Thoroughness of application is required, a 14-year-old tree requiring 15 to 20 gal. for each application.

Treatment for potato rot, A. SEMPOLOWSKI (*Ztschr. Pflanzenkrank., (1894), No. 6, pp. 323–325*).—The author conducted experiments on 10 plats of about $\frac{1}{40}$ acre each for the prevention of potato rot. Plats 1, 4, 7, and 10 were untreated, No. 2 was sprayed with a Bordeaux mixture containing 6 per cent copper sulphate and 6 per cent fresh lime; No. 3 was sprayed with a 6 per cent solution of iron sulphate and lime; No. 5 was sprayed with an 8 per cent Bordeaux mixture; No. 6 was sprayed with an 8 per cent solution of iron sulphate and lime; No. 8 was sprayed twice, first with a 4 per cent Bordeaux mixture, and 2 weeks later with a 6 per cent solution of the same; No. 9 was treated in the same way, iron sulphate being substituted for the copper sulphate.

The potatoes were planted April 19 and made their appearance above ground June 7. The spraying was done June 28, and when a second was given it was applied July 12. The potatoes were harvested September 5. The highest yield as well as per cent of starch was found in plat 2, while the number of diseased tubers was small. The smallest yield was from plats 6 and 9, the strong solutions of iron sulphate having injured the plants, its effect being plainly seen in the brownish color of the leaves 6 days after spraying. Plats 8 and 9 showed the lowest per cent of diseased tubers. The most rotten tubers were found in the unsprayed rows. However, the yield and starch content of each of these plats exceeded those of the treated ones with the exception of plat 2. The author establishes the fact that iron sulphate injuriously affects the growth of the leaves as well as lessens the yield of tubers. A comparative test of 2 per cent solutions of Bordeaux mixture and iron sulphate and lime solution is to be undertaken.

Potato scab, S. B. GREEN (*Minnesota Sta. Rpt. 1893, pp. 222–228*).—Reprinted from Bulletin 32 of the station (E. S. R., 6, p. 57).

Late blight and rot of the potato, S. B. GREEN (*Minnesota Sta. Rpt. 1893, pp. 215–221*).—Reprint from Bulletin 32 of the station (E. S. R., 6, p. 57).

A new barley smut, H. BIEDENKOPF (*Ztschr. Pflanzenkrank., 4 (1894), No. 6, pp. 321, 322*).—The author describes as *Ustilago medians* a new species of smut of barley that from cultures seems to be intermediate in its characters between *U. hordei* and *U. jensenii.* A more critical study of the species is to follow.

List of parasitic plants found near the station, O. LUGGER (*Minnesota Sta. Rpt. 1893, pp. 307–312*).—A list of fungi, embracing about 150 species, is given, arranged in the order of their hosts. The more numerous genera represented are as follows: *Peronospora,* 7 species; *Puccinia,* 18 species; *Cercospora,* 10 species, and *Septoria,* 11 species. There are 35 orders of phanerogams represented in the list of hosts.

New species of fungi, J. B. ELLIS and B. M. EVERHART (*Proc. Phil. Acad. Sci., 1894, III, pp. 322–386*).—Descriptions and critical notes on new species.

Diseases of the vine (Cont.), G. MASSEE (*Gard. Chron., 17 (1895), ser. 3, p. 134*).—A brief description of anthracnose (*Sphaceloma ampelinum*) is given. Dusting plants with equal parts of sulphur and lime is advised. Too free use of fresh stable manure is thought to favor the development of the disease.

Chytridiose of the grape and its treatment, A. PRUNET (*Prog. Agr. et Vit., 12 (1895), No. 3, pp. 73–76; No. 4, pp. 91–98*).

Sulphuric acid for grape anthracnose, L. DEGRULLY (*Prog. Agr. et Vit., 12 (1895), No. 6, pp. 135, 136*).—Ten liters of sulphuric acid to 100 of water gave good results when applied to grapes, equaling the acid iron sulphate solution without the trouble and expense of the copperas.

Report on experiments with "Fostite", 1894, W. M. SCHÖYEN (*Tidskr. norske Landbr., 1 (1894), pp. 441–443*).—The Fostite (90 per cent magnesium silicate, 10 per cent copper sulphate) was applied with some degree of success against fungus diseases of potatoes and other crops.

Observations on the application of fungicides and insecticides (*New York State Sta. Bul. 74, pp. 383–405, figs. 12*).—Illustrations and descriptions are given of various kinds of apparatus for the application of fungicides and insecticides, together with formulas for Bordeaux mixture, kerosene emulsion, and Paris green solutions.

ENTOMOLOGY.

Insect Life (*U. S. Dept. Agr., Division of Entomology, Insect Life, vol. VII, No. 3, pp. 217–280, figs. 10*).—*Special notes* (pp. 217–219).—Under this head are treated the need of quarantine laws in the East, the double-broodedness of the codling moth, the chinch bug in 1894, and reviews of entomological publications.

Damage by the American locust, L. O. Howard (pp. 220–229).—An account of a destructive invasion of *Schistocera americana* in Roanoke County, Virginia, where oats, clover, corn, fruit trees, and other vegetation were defoliated by the insects. Illustrated, descriptive, and life history notes are given and a detailed report upon the attack, by D. W. Coquillett, is included. A mixture of bran, arsenic, and sugar distributed through the fields proved an efficient means of destruction.

Chinch bug observations in Iowa in 1894, H. Osborn (pp. 230–232).—Notes on devastations by this insect—wheat, barley, rye, oats, and corn suffering in the order given. The bugs were found in the vast majority of cases to have hibernated in osage orange hedges. Light, friable soils were most infested.

The hibernation of the chinch bug, C. L. Marlatt (pp. 232–234).—Notes and observations on this point of the life history, the normal hibernating place of the chinch bug being believed to be the dense stools of certain wild grasses, which it is recommended be burned in the winter. The life cycle of the insect for central Kansas is summarized.

A maple pseudococcus, L. O. Howard (pp. 235–240).—Illustrated, descriptive, and life history notes on *Pseudococcus aceris*, a rare scale which occurred on maples in 4 or 5 localities in the northern United States the past season.

Notes on cotton insects found in Mississippi, W. H. Ashmead (pp. 240–247).—A continuation of a paper begun in Insect Life, vol. VII, No. 1 (E. S. R., 6, p. 563). This installment contains an annotated list of the Hymenoptera and Coleoptera found in cotton fields by the writer. The following new genus and species are described: *Chrysopophagus, C. compressicornis, Zachresta dimidiata, Limneria mississippiensis, Lymeon annulicornis, Otacustes atriceps*, and *O. chrysopæ*.

The codling moth double-brooded, C. L. Marlatt (pp. 248–251).—An exhaustive review of the data bearing on this point, with the conclusion that in the greater part of the United States the insect has 2 annual broods, though in the northern States there is but 1, and there are 3 in California.

A new sawfly, which is injurious to hollyhocks, T. D. A. Cockerell (pp. 251–253).—A technical description of *Nematoneura malvacearum*.

Notes on Hylesinus sericeus, E. A. Schwarz (pp. 254–256).—Notes on the habits of this scolytid infesting Engelmann's spruce (*Picea engelmanni*) in the Wahsatch Mountains, Utah. An illustration is given of the workings under the bark.

A new parasite of Mytilaspis pomorum, L. O. Howard (p. 256).—Technical description of *Chiloneurus diaspidinarum*, a hymenopterous parasite of the apple oyster-shell bark louse.

The patent on the hydrocyanic acid gas process declared invalid, D. W. Coquillett (pp. 257, 258).—Note on a recent court judgment on this point in California.

A new pear insect (pp. 258–260).—Notes on *Agrilus sinuatus*, a flat-headed borer imported from Europe, that has caused considerable damage to pear trees in New Jersey.

Scorpions, centipedes, and tarantulas (pp. 260–263).—Notes on the venom of these animals, with letters from 2 entomologists who had been stung by scorpions in the Tropics.

General notes, and notes from correspondence (pp. 263–280).—Among these may be noted the following: Grain insects in mills, the carnation twitter again, legislation against insects in British Columbia, a new department of the Pasteur Institute, some South Australian matters, coöperative work against insects, a New Zealand moth-catching plant, the army worm in 1894, abundance of *Charæas graminis* in Scotland, two more important Vedalias, damage by the brown sap chafer, abundance of an imported snout beetle in Maine, damage to clover in Michigan, a new cotton insect in Texas, the pear midge in England, destructive grasshoppers in New York, an important scale insect on cottonwood, the spider which bites, cicada chimneys, bird lice as mutualists, occurrence of the pear-leaf blister mite upon the Pacific Coast, maggots in poor butter, new habitats for the Florida red scale, the potato-scab gnat in Missouri, Oklahoma food of the harlequin cabbage bug, the apple maggot in North Carolina, the sugar-cane weevil in the Fiji Islands, horn fly on horses again, the barnacle scale in Louisiana, and the hen flea on horses.

Report of the entomologist, F. L. HARVEY (*Maine Sta. Rpt. 1893, pp. 146–151, 159–180, figs. 16*).—Illustrated, descriptive, life history, and remedial notes on the Angoumois grain moth (*Gelechia cerealella*), lime-tree winter moth (*Hybernia tillaria*), apple-leaf bucculatrix (*Bucculatrix pomifoliella*), disippus butterfly (*Limenitis disippus*), May beetle (*Lachnosterna fusca*), bean weevil (*Bruchus obtectus*), pear-blight beetle or shot-borer (*Xyleborus pyri*), and carrot fly (*Psila rosæ*).

The apple-leaf bucculatrix was observed damaging apple trees in the State for the first time, and its habits were especially investigated. The damage was done in early summer and it is believed that there is but one brood in Maine. Jarring the larvæ from the trees, spraying with kerosene emulsion in the winter and when the larvæ hatch, and hand picking the cocoons are recommended. Kainit, kerosene emulsion, and turning hogs in infested fields are suggested against the larvæ of the May beetle. The bean weevil was quite injurious, and it is suggested that infested seeds be thrown into hot water for a few minutes or heated to 145° F. for an hour. Bisulphid of carbon is also suggested. The pear-blight beetle was noticed for the first time attacking fruit trees, it having previously been noticed only on forest trees. It is recommended that blighted twigs or limbs be cut off promptly and burned. The larvæ of the carrot fly were found burrowing in barrels of carrots. Treating the infested roots with hot water is advised. Pouring kerosene emulsion along the rows of plants during the growing season it is thought may be advantageous.

Gas treatment for destroying scale insects on citrus trees, A. CRAW (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 105-109, pls. 2*).—Directions for the preparation of hydrocyanic acid gas and its application, the manufacture of the tents and other apparatus being detailed. It is advised that the tents be treated with a light coat of linseed oil, or, better, with a watery extract of the common prickly pear cactus (*Opuntia engelmani*) combined with glue and ocher or Venetian red.

Experiments were made in spraying apple trees with a solution of Paris green and Bordeaux mixture as a combination remedy against codling moth and apple scab.

Beneficial insects, A. CRAW (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 96–105, pls. 3*).—Descriptive notes and colored illustrations of the following insects, native and imported, preying upon various scale insects: Two-spotted ladybird (*Adalia bipunctata*), *Anatis subvittata*, twice-stabbed ladybird (*Chilocorus bivulnerus*), ashy-gray ladybird (*Coccinella abdominalis*), California ladybird (*C. californica*), 22-spotted leis (*C.* (*Leis*) *conformis*), eyed ladybird (*C. oculata*), blood-red ladybird (*C. sanguinea*), Julian's banded ladybird (*C. trifasciata juliana*), Pilate's ladybird (*Exochomus pilatei*), convergent ladybird (*Hippodamia convergens*), ambiguous ladybird (*H. ambigua*), *Hyperaspis lateralis*, striped ladybird (*Megilla vittigera*), Koebele's ladybird (*Novius koebelei*), six-spotted orcus (*Orcus australasia*), steel-blue ladybird (*O. chalybeus*), 20-spotted ladybird (*Psyllobora 20-maculata*), brown-necked ladybird (*Rhizobius toowoombæ*), black ladybird (*R. ventralis*), Australian ladybird (*Vedalia cardinalis*), a lepidopterous enemy of the black scale (*Thalpochares coccophaga*), lace-winged fly (*Chrysopa californica*), brown lace-winged fly (*Hemerobius*), spine-legged soldier bug (*Sinea spinipes*), gray soldier bug (*Euschistus tristigmus*), and syrphus fly (*Catabomba pyrastri*).

Entomology and quarantine, A. CRAW (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 79–90, figs. 3*).—A report of the inspection of steamers and their cargoes to avoid the introduction of injurious insects. Details of the work of fumigation are given. Notes are included on some of the beneficial insects of the State, chiefly ladybirds, and on some of the injurious insects and their parasites. Descriptive and remedial notes are given.

The silk industry, FRY and JAMES (*Agl. Gaz. N. S. W., 5 (1894), No. 11, pp. 812–817*).—A general article to show that the industry could flourish in Australia.

Note on Pulex pallidus and Sarcopsylla gallinacea, from Transcaspia, J. WAGNER (*Hor. Soc. Ent. Ross., 28 (1894), No. 3 and 4, pp. 440–443*).—Gives description and figures of the chicken flea from specimens found on owls in Middle Asia. The species is identical with that occurring in Florida.

On a new species of Ixodidæ from Congo, J. MARTIN (*Ann. Sci. Nat., 18 (1894), 2d ser., pp. 267–277, pl. 1*).—This contains a description of *Amblyomma quantini* and a partial bibliography of *Ixodidæ*.

Furniture beetles, S. L. MOSLEY (*The Naturalists' Journal, 4 (1895), No. 31, pp. 14, 15*).—Ravages of *Anobium domesticum*, *Xertobium tesselatum*, and *Ptilinus pectinicornis* in the wood of furniture, etc. Paraffin is recommended as a remedy.

Scale insects, A. CRAW (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 90–96, figs. 8*).—Descriptive and life history notes on an elm scale (*Gossyparia ulmi*), depressed scale (*Lecanium depressum*), pine tree scale (*L. insignicolla*), black scale (*L. oleæ*), orange chionaspis (*Chionaspis citri*), long scale (*Mytilaspis gloverii*), and purple scale (*M. citricola*). Against the elm scale a resin wash is recommended in the winter and kerosene emulsion in the spring and summer. Formulas are given for the preparation of these insecticides.

Observations on Physapoda in the summer of 1893, F. TRYBORN (*Ent. Tidskr., 15 (1894), No. 1 and 2, p. 41*).

The red gooseberry mite (Bryobia nobilis), F. THOMAS (*Whittmark's Gartenflora, 43 (1894), pp. 488–490*).

Injury to gooseberry plants by Bryobia ribis, F. THOMAS (*Mitt. Thür. Bot. Ver., 2d ser., 6 (1894), pp. 10, 11*).

The oviposition of Melitara prodenialis, H. G. HUBBARD (*Proc. Ent. Soc. Wash., 3 (1895), No. 3, pp. 129–132*).—Description and figure of the peculiar mode of oviposition of this moth, which is greatly destructive to cultivated cacti.

Treatment of vines infested with phylloxera with mulches of peat impregnated with schists, F. DE MÉLY (*Compt. Rend., 120 (1895), No. 2, pp. 67–69*).

Legislation against plant pests, C. S. SARGENT (*Garden and Forest, 8 (1895), No. 362, pp. 40, 41*).

"Insect Lime," J. B. SMITH (*Ent. News, 1895, Feb., pp. 46, 47*).—Recommends it for protecting fruit trees.

On an Acarien parasite of Lampyris splendidula, A. GRUVEL (*Compt. Rend., 120 (1895), No. 3, pp. 161, 162*).

The use of parasitic and predaceous insects, C. M. WEED (*Amer. Nat., 29 (1895), No. 337, pp. 69, 70*).

Rhizobius ventralis, B. M. LELONG (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 426–432*).—An article on the introduction of the black ladybird. Extracts from letters of horticulturists in various parts of the State are included, testifying to the value of the ladybird in destroying the black scale.

Beneficial insects, A. KOEBELE (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 145–150*).—General notes on some of the natural parasites of coccids injurious to fruit trees in Australia, with notes on their habits, some of the scale insects, and the condition of fruit growing in that country.

Report of the government entomologist of Sweden for the year 1893, S. LAMPA (*Ent. Tidskr., 15 (1894), No. 1 and 2, pp. 1–40*).

The classification of insects and their relation to agriculture, O. LUGGER (*Minnesota Sta. Rpt. 1893, pp. 75–143, figs. 81*).—A reprint of Bulletin 28 of the station (E. S. R., 4, p. 932).

On economic entomology and mycology in the United States and what we can learn therefrom, M. HOLLRUNG (*Jahrb. deut. landw. Ges., 9 (1894), pp. 60–70*).

FOODS—ANIMAL PRODUCTION.

Analyses of cattle foods, W. H. JORDAN, J. M. BARTLETT, and L. H. MERRILL (*Maine Sta. Rpt. 1893, pp. 25–36*).—This includes studies on the composition of corn fodder and silage from different varieties, the comparative composition of large Southern corn and the smaller Maine field corn, the influence of maturity upon the composition of the corn plant, the constituents of the nitrogen-free extract, and the effect of slow drying upon a sample of a succulent plant (p. 744).

Observations have been made for 5 years on the composition of large Southern corn and of the smaller native corn grown in Maine. The latter matures, but the former has to be cut when immature. The average composition of the dry matter of the 2 varieties is given as follows:

Composition of the dry matter of 2 varieties of corn.

Average for 1892 and 1893.	In 100 parts water-free substance.				
	Ash.	Protein.	Fiber.	Nitrogen-free extract.	Fat.
Southern corn, immature	7.76	11.72	27.70	50.54	2.28
Maine field corn, mature	6.05	10.94	19.79	60.33	2.89
Differences	+.71	+.78	+7.91	—9.89	—.61

"The Maine field corn, which reaches maturity, contains the larger percentage of dry matter. . . .

"The dry substance of the larger and immature corn contains more ash, protein, and fiber and less nitrogen-free extract and fat. The much larger percentage of fiber and greatly less percentage of nitrogen-free extract are the noteworthy differences."

The Maine field corn was cut at 5 different dates from August 15 to September 21 and samples of each cutting analyzed. These analyses show that as the corn approaches maturity there is a continuous and large increase in the percentage of dry matter, due principally to an increase in nitrogen-free extract. To determine if possible what components were responsible for this increase in nitrogen-free extract determinations were made of the starch by means of diastase and the acid method and of the sugar. These showed "that while a decrease in sugar occurred with the maturing of the ear, this was much less than the corresponding increase of starch, so that maturity shows a large excess over any other period of the more valuable carbohydrates."

A comparison of the starch and sugar in immature Southern corn and mature native corn, both grown in Maine, showed the following:

Sugars and starch in the immature and mature corn plant.

	Parts in 100 of water-free substance.				Parts of sugars and starch in 100 parts of nitrogen-free extract.
	Sugars.	Starch.	Total sugars and starch.	Total nitrogen-free extract.	
Southern corn, immature, no ears, 4 samples	12.85	1.07	13.92	50.55	27.5
Maine field corn, mature, full ears, 4 samples	13.32	14.02	27.34	60.33	45.3
Excess in the Maine field corn	0.47	12.95	13.42	9.78	17.8

"There is a constant and striking difference between the percentages of starch in the Southern corn and in the Maine field corn. They are much larger in the latter kind. This is due undoubtedly to greater maturity. Only a small amount of starch appears to be deposited in the stalk and leaves, its rapid formation and storage in the plant apparently not beginning until the later development of the fruit or kernels."

The digestibility of the pentose carbohydrates, W. E. STONE and W. J. JONES (*Maine Sta. Rpt. 1893, pp. 44–56*).—This is a reprinted article,[1] and relates to the study of the pentose carbohydrates in a large number of feeding stuffs fed in digestion trials at the Maine Station and in the feces from the same.

"The grasses make the largest showing, but in the majority of samples the pentosans amounted to from 20 to 30 per cent of the non-nitrogenous extractive matter. . . .

"The data for the pentosans in feces of sheep, excluding the data for *Calamagrostis canadensis*, which evidently present something anomalous, shows 58.2 per cent of pentosans to have been digested and 41.8 per cent undigested.

"These results are worthy of consideration. Twenty of the best known food stuffs for cattle are here shown to contain a minimum of from 6 to 16 per cent of their dry weight in pentosans, of which an average of only 58.2 per cent is found to be digestible. It appears, then, that while these bodies are to be for the present classified among the carbohydrates, they are really much less digestible, and hence of less food value, than the better known members of this group, such as starch, sugar, etc. In many cases the indicated digestibility is even less than that assigned to the fiber of the same materials, and the average of all the experiments is but little higher than the corresponding average for the fiber."

Effect of slow drying upon a sample of a succulent plant, W. H. JORDAN, J. M. BARTLETT, and L. H. MERRILL (*Maine Sta. Rpt. 1893, pp. 35, 36*).—A sample of about 500 lbs. of field corn was chopped fine and spread out on a scaffold to dry, and a subsample was taken and dried rapidly in a steam closet in the laboratory. Analyses of the rapidly and slowly dried samples are given.

"It seems that for each 100 lbs. of green corn 3.58 per cent of dry matter was lost in the process of slow drying under the most favorable circumstances. This was 14.13 per cent of the total dry matter in the fresh plant, which means that of each 100 lbs. of dry substance originally in the plant only 85.87 lbs. were saved.

---

[1] Agl. Sci., 7 (1893), No. 1, p. 6.

"It is interesting to note that this loss falls almost entirely on the nitrogen-free extract, or carbohydrates, more than two thirds of it being actually accounted for by the diminished percentage of sugars."

Effect of watering, whether before or after eating or ad libitum, on digestibility of the food and nitrogen exchange, S. GABRIEL and H. WEISKE (*Landw. Vers. Stat., 45, No. 3 and 4, pp. 311–323*).—To determine whether it was immaterial when animals were watered, as shown by the amount of water taken, the utilization of the food, and the nitrogen exchange of the body, a trial was made with 2 grown sheep, lasting from June 2 to 29, divided into 3 periods. In the first period water was kept before the sheep all the time; in the second No. 1 was watered before feeding and No. 2 after; and in the third the order was reversed. The food consisted uniformly of 800 gm. of meadow hay and 250 gm. of whole oats per sheep daily, fed in 3 portions. The quantity of water drunk and the amount and composition of the solid and liquid excreta were determined for each sheep in each period. The average results follow:

Average water consumption, nitrogen exchange, and nitrogen storage per sheep daily.

Manner of watering.	Amount of water drunk.		Nitrogen exchange of body.[1]		Nitrogen stored in body.	
	No. 1.	No. 2.	No. 1.	No. 2.	No. 1.	No. 2.
	Cc.	*Cc.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*
Ad libitum	1,804	2,333	7.34	8.21	1.59	1.22
Before feeding	1,596	1,765	7.88	8.18	1.00	1.30
After feeding	1,870	2,127	7.89	8.26	1.27	1.38

[1] As shown by nitrogen in urine.

Digestibility of ration under different methods of watering.

Manner of watering.	Protein.		Fat.		Fiber.		Nitrogen-free extract.	
	No. 1.	No. 2.	No. 1.	No. 2.	No. 1.	No. 2.	No. 1.	No. 2.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Ad libitum	57.37	60.55	63.59	65.96	61.73	53.48	66.78	68.52
Before feeding	57.04	60.89	65.98	66.88	52.90	60.26	66.14	64.17
After feeding	58.85	61.94	64.33	66.33	57.89	59.54	65.44	67.15

It will be seen that sheep No. 1 invariably drank more water than sheep No. 2, which is believed to be a matter of individuality. Both sheep drank less water when it was given before feeding than when given *ad libitum* or after feeding. The average difference amounted to 13 per cent with No. 1 and 21 per cent with No. 2. There was no apparent connection between the manner of watering and the nitrogen exchange, although this was somewhat greater throughout in the case of No. 2, due, it is suggested, to the greater water consumption. Likewise in the rate of digestibility there were no regular differences that could be attributed to manner of watering.

The conclusion is reached that under the conditions here prevailing there is no difference in the rate of digestibility of the food, production, etc., whether the animals are given water *ad libitum* or before or after eating.

Digestion experiments, W. H. JORDAN (*Maine Sta. Rpt. 1893, pp. 38–43*).—The results are given of digestion trials with sheep on Southern corn fodder, field corn fodder, sweet corn fodder, Southern corn silage, and field corn silage. No data are given except the composition of the materials as fed and the digestion coefficients found. The latter were as follows:

Digestion coefficients of corn fodder and corn silage.

	Dry matter.	Organic matter.	Ash.	Protein.	Fiber.	Nitrogen-free extract.	Fat.
Southern corn fodder, 1891	61.3	62.8	43.1	63.4	65.7	61.0	59.0
Field corn fodder, 1891	72.7	74.2	50.7	67.6	78.6	73.8	64.7
Sweet corn fodder, 1891	70.9	72.7	44.0	71.5	74.6	73.1	77.0
Southern corn silage, 1892	64.4	65.8	48.2	64.8	66.7	65.4	67.8
Field corn silage, 1892	78.0	80.2	41.3	68.0	77.9	83.1	80.9
Do	76.0	77.9	36.6	73.3	77.8	78.5	80.9
Field corn fodder, 1893	69.8	71.4	54.5	70.4	72.3	71.3	67.3
Do	69.7	73.6	20.0	68.6	70.7	76.7	73.7

During the past 4 years 37 digestion trials have been made at the station on corn fodder and corn silage. The results of these are compared with the digestion coefficients for timothy hay, wheat bran, and corn meal.

"These figures show beyond question that corn fodder well preserved and corn silage have a high digestibility as compared with hay. To this fact should be attributed in large measure undoubtedly the great favor with which the corn plant, as now preserved in the silo is regarded by dairymen as milk-producing food. What has been supposed by many to be due to the peculiar influence of the fermentations in the silo, should more properly be credited to the superior food properties of the plant which the silo conserves so efficiently, and which would be equally valuable when preserved as completely in any other manner."

A comparison is also made of the digestibility of the fodder and silage from native field corn and from Southern corn grown in Maine. The comparison is as follows:

Comparative digestibility of 2 varieties of corn grown under similar conditions.

	Dry matter.	Organic matter.	Ash.	Protein.	Fiber.	Nitrogen-free extract.	Fat.
Field corn fodder and silage, 7 samples, 17 trials	72.3	74.6	36.8	65.1	76.5	75.5	74.9
Southern corn fodder and silage, 5 samples, 12 trials	64.6	66.5	39.7	59.6	71.0	65.2	66.3
Difference in favor of the field corn	7.7	8.1	....	5.5	5.5	10.3	8.6

"It is certainly a matter of some importance to Maine farmers that the smaller variety of corn, which matures in this latitude, should prove to be more digestible to the extent of about 8 per cent of the total dry matter.

"The nitrogen-free extract appears to show a greater difference of digestibility than other portions of the plant, and it is here that we must look for at least a partial explanation of the fact under discussion. . . .

"Several examinations of the feces in these experiments have failed to show the presence of sugars or starch, the diastase test being employed for the latter. These carbohydrates being entirely soluble in the digestive fluids, as it was reasonable to expect, their presence in these foods in greatly varying quantities must certainly cause corresponding variations in the digestibility of the nitrogen-free extract, and consequently of the total dry matter, other things being equal. That this is so is easily seen from the figures presented."

Steer feeding, A. A. MILLS (*Utah Sta. Bul. 35, pp. 23*).—Three lots of 4 steers each were fed alike on mixed hay from November 29 to December 20. From then until April 11 lot 7 had mixed hay alone; lot 8, hay with straw, alfalfa, or clover, and 3 lbs. grain per head for 1 month; and lot 9 had hay and 3 lbs. grain (bran, wheat, and barley) per head daily. In the finishing period, April 11 to May 16, all received alike 3 lbs. of grain (bran and wheat) per head, 10 lbs. roots, 3 lbs. straw, and hay *ad libitum.*

The steers were kept in yards with open sheds. The gains in weight, food eaten, and financial results are tabulated. From November 29 to April 11, lot 7 (mixed hay) gained 574 lbs. in all; lot 8, 270 lbs., and lot 9 (hay and grain), 252 lbs. During the final period lot 7 gained 39 lbs.; lot 8, 11 lbs., and lot 9, 91 lbs. For the whole trial the average cost of food per pound of gain was 7.2 cts. for lot 7, 10.71 cts. for lot 8, and 8.51 cts. for lot 9. With steers at 2½ cents per pound there was a loss with all the steers, which was least with lot 9.

Steers fed moderately well for 12 weeks.—Six lots of 3 steers each which had been used in an experiment with alfalfa, reported in Bulletin 31 of the station (E. S. R., 6, p. 203), were fed from February 21 to May 16 variously on hay with silage, roots, or straw, and 4 lbs. of grain per head daily; or hay and roots with 4, 6, or 8 lbs. of grain. The grain was a mixture of bran, barley, and wheat. The coarse fodder was fed *ad libitum.* The gains, food eaten, and financial results are tabulated.

"Of the 3 sets of steers fed either roots, silage, or straw as an appetizer, those fed the roots gained most, with straw second and silage third.

"Of steers fed 4, 6, and 8 lbs. of grain per day, respectively, the gain increased as the amount of grain fed was increased; the cost of the daily ration increased likewise; while the cost of 1 lb. of gain decreased as the amount of grain fed increased."

Feeding experiments with cows, W. H. JORDAN (*Maine Sta. Rpt. 1893, pp. 66–82*).—*Relative feeding value of Southern corn silage and Maine field corn silage* (pp. 66–73).—The object of this experiment was to compare silage from native Maine corn and from large Southern corn grown in Maine. Five cows were fed in 3 periods of about 1 month each. In the first and last periods about 40 lbs. of Southern corn silage was fed per day, and in the second period about 30 lbs. of native corn silage. The other foods consisted of corn meal, bran, gluten meal, and cotton-seed meal, with barley hay in the first 2 periods and timothy hay in the last. The digestible food material in the daily ration of the 3 periods was 14.23, 16, and 14 lbs., respectively. The analyses of the feeding stuffs given, the amount of nutrients consumed, weight of cows, and the yield and composition of the milk are tabulated.

"The cows lost from 15 to 30 lbs. weight in passing from the first to the second periods, and this loss was partially regained during the third period. These changes in live weight can be readily explained by the less weight of silage eaten in the second period, with no marked change in the quantity of water drank in any period. . . .

"When we see that in the second period of this experiment practically the same weight of milk was produced, and that owing to an increase in the dry matter of the milk there was actually a larger production of milk solids, we have good presumptive evidence that the ration containing the 30 lbs. of [native] field corn silage was more efficient than the previous ration containing 40 lbs. of Southern corn silage. This evidence is strengthened by the fact that when in the third period a return is made to the Southern corn silage the yield of milk solids is decidedly diminished.

"[The indications are] that, pound for pound, the Maine field corn silage was worth more than the Southern corn silage, and that the difference was practically in the proportion of the amount of digestible dry substance in the 2 materials. This is the result which a careful consideration of the facts learned in other ways would lead us to expect."

The influence of widely differing rations upon the quantity and quality of milk (pp. 73–82).—An experiment is reported with 3 cows, covering 3 periods of 35 days each, in which the following rations were compared:

Ration 1:

Timothy hay	*ad lib.*
Corn meal	2 pounds.
Cotton-seed meal	2 pounds.
Gluten meal	2 pounds.

Ration 2:

Timothy hay	*ad lib.*
Corn meal	6 pounds.

Cow A received ration 1 during the first and third periods and ration 2 during the second period, and cows R and L T received ration 2 during the first and third periods and ration 1 during the second period. The nutritive ratio of ration 1 was 1 to 6.7, and of ration 2, 1 to 12.3. Both rations furnished practically the same amount of digestible material. The amounts of food eaten and the yield and composition of the milk, melting point, volatile acids, and iodin equivalent of the butter are tabulated for each cow. The yield of milk and of milk solids was as follows:

Yield of milk and milk solids on nitrogenous and carbonaceous rations.

	Daily yield of milk.			Daily yield of milk solids.		
	Nitrogenous ration.	Corn-meal ration.	Excess with nitrogenous ration.	Nitrogenous ration.	Corn-meal ration.	Excess with nitrogenous ration.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
Cow A	25.6	20.0	5.6	3.61	2.68	0.93
Cow R	20.7	15.2	5.5	2.88	2.07	0.81
Cow L T	19.1	15.6	3.5	2.72	2.10	0.62

"The cows did not vary greatly in body weight, but their general appearance showed less thrift while being fed the corn-meal ration.

"The yield of milk from the nitrogenous ration was from one fifth to more than one third larger than that from the corn-meal ration, the excess ranging with the 3 cows from 20 per cent to 36 per cent, or an average of about 5 lbs. of milk per day.

"In general the milk was materially richer while the cows were fed the ration rich in protein, though with one cow it showed the largest percentage of solids during the third period while she was eating the corn-meal ration. With the other two cows the influence of the mixture of cotton-seed meal, gluten meal, and corn meal in increasing the per cent of solids of the milk seemed quite marked.

"The daily yield of milk solids was from 30 to 40 per cent greater with the more nitrogenous ration.

"The composition of the milk solids seemed to be independent of the ration. In general the proportion of fat increased throughout the experiment without regard to what the cows were fed, and no evidence is furnished in support of the notion that by changing the food it is possible to produce more butter fat without an accompanying increased production of the other milk solids. In other words, it appears that the most profitable food for butter production will also be most profitable for the milk farmer or cheese maker. The relation of fat to the other solids seems to be determined by the animal or by certain unknown conditions of environment rather than by the food.

"So far as could be learned by chemical tests, the butter made from the 2 rations was not greatly different."

Dairy herd record for 1892, T. L. HAECKER (*Minnesota Sta. Rpt. 1893, pp. 313–324*).—A record for the year of 27 cows, including Jerseys, Guernseys, Holsteins, Polled Anguses, Shorthorns, and grades. This shows for each cow the date of calving, change in weight, monthly yield and composition of milk, and monthly and yearly yields of butter.

"The fat for the entire herd ranged from an annual average of 3.34 to 6 per cent. This marked difference is clearly a breed characteristic. . . .

"While there is a general tendency for the milk to grow richer in fat as the period of lactation advances, this change is not as great or as uniform as is generally supposed. [The individual records for January, March, June, and July show that] in January the daily average in milk of the 17 cows amounted to 423 lbs.; in March it shrunk to 354.3 lbs.; while in June, when the cows were in pasture, it increased to 375 lbs., and in July, when pastures began to be dry, there was again a shrinkage to 301.6 lbs., showing that the succulent food in June materially increased the flow of milk. In January the average per cent of fat in the milk was 4.55, in March it rose to 4.95, and in June it dropped to 4.49; that is, after the expiration of 6 months the average per cent of fat was less by 0.06 per cent, showing that feed exercised a greater influence in the per cent of fat than did the advanced period of lactation. The fact that the per cent of fat in July, when the Kentucky blue grass, of which the pasture was composed, was dry, rose to 4.81, gives additional evidence that the variation in the fat was largely due to feed influences. .

"[The butter fat record] shows a gradual decrease in the amount of fat, as the period of lactation advances, and also shows that this shrinkage takes place very slowly and gradually when cows are of the proper dairy breeding type. . . .

"Comparing the annual butter yield with the live weight, the registered Jersey, Pride, is in the lead, making 0.46 lb. of butter for every pound of live weight, followed by the grade Jersey, Marie, with 0.44; the grade Guernsey, Olive, 0.44; the grade Jersey, Beckley, with 0.43; then Sweet Briar, Rose, and Rossie, 0.40 lb. each. . .

"Our best cows, the annual butter product of which exceeds 40 per cent of the live weight, are small or medium in size, though good ones are found among the larger."

Feeding experiments with pigs, W. H. JORDAN (*Maine Sta. Rpt. 1893, pp. 82–95*).—These experiments include comparisons of breeds and a comparison of skim milk, pea meal, and corn meal with a mixture of equal parts of pea meal, oat meal, and corn meal on 3 different breeds of pigs. The relation of the food to growth in different breeds is shown in the following summary:

Relation of food to growth in pigs (digestible organic material for each pound of gain).

Experiment.	Cheshire.	Poland China.	Yorkshire.	White Chester.	Jersey Red.	Berkshire.	Tamworth.	Tamworth-Berkshire.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
1890	2.88	2.73	2.50	2.50		2.45		
1891	3.12			2.78	2.93			
1891-'92, early growth							3.18	2.48
1891-'92, later growth							3.71	2.89
1892, period 1						2.36	2.11	2.03
1892, period 2						3.80	3.20	3.20
1892, period 3						5.87	4.03	3.52
1892, period 4						3.80	4.19	4.02
1892, average 4 periods						3.40	3.21	3.00

"These experiments furnish no evidence of the superior producing capacity of any one of the breeds tested. . . . It is certainly true of the Tamworth-Berkshire cross that the animals were finely formed and vigorous, and they certainly used food more economically than either the pure bred Tamworths or Berkshires. This cross has been admired by all who have seen it, and the market quality of their carcasses was highly commended.

"[The butcher's analysis of the carcasses] do not warrant the claim that any one of the breeds compared possesses superior market qualities over all the others. The Tamworth's gave a somewhat larger percentage of lean cuts and the Tamworth-Berkshire cross a larger proportion of salting pork. The differences are small, we may believe, compared with those which may be caused by age, food, or individual variations."

In a comparison of the dry matter of skim milk with the digestible matter of pea meal 2 lots of pigs were selected from the same litters and fed rations composed of skim milk, pea meal, and corn meal, or rations in which pea meal or oat meal was made to take the place of skim milk in the proportion of digestible substance in the two. The rations contained practically the same amounts of digestible matter. Tamworths, Berkshires, and Tamworth-Berkshires were represented.

"It is very plain that for young pigs the rations containing skim milk proved superior to those containing the nitrogenous vegetable foods as a substitute. But with the older animals the substitution of pea meal or pea and oat meal for the skim milk, wholly or in part, did not materially change the rate of growth or its relation to the digestible food consumed.

"In a single case an exception occurs, viz: Period 3 with the Berkshires in the 1892 experiment, where the pure grain ration seemed to check the growth of the pigs. In all other cases the amount of digestible food seems to be the practical measure of efficiency, whether its source be animal or vegetable."

Relative value of corn and oats for horses, A. A. MILLS (*Utah Sta. Bul. 36, pp. 12*).—Two teams of work horses were divided into 2 lots, one horse for each team being in each lot. Fifteen pounds of mixed hay and 3 lbs. of wheat or bran per head were given to the horses in both lots, and those in one lot received 6 lbs. of corn, while those in the other lot received 6 lbs. of oats per head. The grain was ground and mixed before feeding. The trial lasted from April 18 to September 26, and the rations were reversed several times during the trial. Grouping the changes in weight according to the kind of feed, "It will be seen that those on the oat ration lost 47 lbs., while those on the corn ration gained 29 lbs., thus favoring the corn ration by a total of 76 lbs. . . . The corn contained 323.77 lbs. more digestible matter than did the oats. This is just about sufficient to account for the excess of gain of the corn-fed lot over the oat-fed."

Reference is made to previous experiments bearing on this subject published in the Annual Report of the station for 1892 and Bulletin 30 (E. S. R., 5, p. 77, and 6, p. 240).

"To sum up the 3 experiments, we find: First, that during the summer corn and timothy were not so good as oats, wheat, and clover in maintaining the weight of horses; second, that during the winter corn and timothy did as well as oats, clover, and timothy in maintaining the weight of horses; third, that during the spring and summer corn, wheat, or bran and mixed hay produced more gain than oats, wheat, or bran and mixed hay."

The effect of different acids on pepsin digestion, M. HAHN (*Virchow's Arch. path. Anat. und Physiol., 137, pp. 597–604; abs. in Chem. Centbl., 1894, II, No. 14, p. 618*).—The effect of sulphuric, nitric, phosphoric, boracic, oxalic, citric, and tartaric acids was compared with that of hydrochloric acid, in a 0.281 per cent digestive solution, on the following substances: (1) Albumen solution, prepared by neutralizing egg albumen with dilute hydrochloric acid; (2) moistened fibrin; (3) dry fibrin; and (4) coagulated egg albumen.

The results showed that the acids employed had different effects, but that the hydrochloric acid was the most advantageous in the digestion of albuminoids. The organic acids taken as a whole were less effective in digestion than the inorganic acids. Only in the case of fibrin were tartaric and oxalic acids of value. The order of effectiveness of the mineral acids on albumen solution was hydrochloric acid, nitric acid, sulphuric acid, and phosphoric acid. When moistened fibrin was used phosphoric acid stood at the head. The boracic acid was of no value to digestion, which was to be expected. It gives insoluble precipitates with most albuminoids, and, like all antiseptics, retards the action of the ferments. As a practical result of these studies it follows that phosphoric acid is best fitted to take the place of hydrochloric acid in pepsin digestion. Although this had only weak effect on the albumen in solution, which forms the smaller part of our food, it had a noticeable effect in the case of solid albuminoid bodies.

Foods, nutritive value and cost, W. O. ATWATER (*U. S. Dept. Agr., Farmers' Bul. 23, pp. 32*).—This is a popular bulletin dealing with the nutrition of the human body, the composition and fuel value of food, nutritive value of different food materials, digestibility of food, dietaries and dietary standards, pecuniary economy of food, waste of food, and food and health. An appendix gives the composition of a large number of food materials, dietary standards, and 18 suggested dietaries with their composition.

Chemical composition of foods, E. F. LADD (*North Dakota Sta. Bul. 15, pp. 49-61*).—Analyses with reference to feeding value are given of timothy, orchard grass, Kentucky blue grass, mixed grasses, prairie hay, millet, medium red clover, alsike clover, alfalfa, wheat straw, oat straw, corn silage, oats, wheat, wheat screenings, wheat bran, linseed meal, and sedge seed; and analyses with reference to fertilizing ingredients of timothy, orchard grass, Kentucky blue grass, medium red clover, alsike clover, and alfalfa.

The composition of fodders, wheat, and milled products, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 41-49*).—A reprint from Bulletin 27 of the station (E. S. R., 4, p. 733).

Stock feeding, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1893, pp. 13-24*).—This is a popular article on the principles of scientific feeding, composition of feeding stuffs, feeding standards, etc.

Digestion experiments, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 3-40*).—A reprint of Bulletin 26 of the station (E. S. R., 4, p. 733).

Mangels and sugar beets vs. silage, H. J. WATERS and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, pp. 37-52*).—This is a reprint of Bulletin 26 of the station (E. S. R., 6, p. 446).

Wheat feeding in Oklahoma, J. C. NEAL (*Oklahoma Sta. Bul. 13, pp. 73-76*).—Compiled information on the subject of feeding wheat to different kinds of farm animals.

On the comparative value of rape-seed cakes, V. STEIN (*Tidsskr. Landökon, 13 (1894), pp. 709-721*).

Colored rape-seed cakes, V. STEIN (*Landmandsblade, 27 (1894), pp. 765-767*).—The author calls attention to the artificial coloring of rape-seed cake, practiced to obtain the desired green color of the cakes and to disguise the admixture of inferior seed. The watery extract of the cakes gives strong reaction for lime, and is alkaline, while that of pure seed is acid.

The meat meal of commerce, A. ANDOUARD (*Ann. Agron., 21 (1895), No. 1, pp. 34-37*).—The food value of this material is briefly discussed, and danger from poisonous products of fermentation, and possibly the disease germs which it may contain, warned against.

Influence of quantity of food upon economy of milk and butter production, H. J. WATERS, W. H. CALDWELL, and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, pp. 24-36*).—A somewhat less detailed account of this experiment was given in Bulletin 24 of the station (E. S. R., 5, p. 596).

Practical rations for lambs, W. M. HAYS (*Minnesota Rpt. 1893, pp. 193-200*).—A reprint of Bulletin 31 of the station (E. S. R., 5, p. 1083)..

History of nutrition, L. BOURDEAU (*Histoire de l'Alimentation. Paris: 1894, pp. 372*).

The cost of keeping dry cows (*Landmandsblade, 27 (1894), pp. 783-786*).

Sheep raising, H. NATHORST (*Stockholm: 1894, pp. 173*).

VETERINARY SCIENCE.

Tuberculosis, E. P. NILES (*Virginia Sta. Bul. 39, pp. 43–54*).—This is a general discussion of tuberculosis. The results of a tuberculin test of the station herd and of one other herd are briefly stated, and attention is called to the fact that 1 animal which on *post-mortem* examination showed tuberculous lesions afforded when injected with tuberculin a reaction of only 1.1 degree.

DAIRYING.

Waste of fat in skim milk by the deep-setting process, W. H. JORDAN and J. M. BARTLETT (*Maine Sta. Rpt. 1893, pp. 95–100*).—This is a reprint of Bulletin 5 of the station (E. S. R., 5, p. 999), with a discussion of the necessity of submerging cans as compared with sinking them in the water to the depth of the milk in the can. The data presented in Bulletin 5 are considered with reference to this point. As a rule the skim milk from cans entirely submerged contains slightly less fat than that from cans not submerged or sealed.

"The value of submerging as a means of decreasing the waste of fat in the skimmed milk does not become apparent through the foregoing figures. It should be remembered, however, that in all these cases ice was used and kept in the tanks all the time. If this were not done the chances would appear to be in favor of submerging, because the greater the volume of water the less its temperature would be raised by cooling the warm milk."

Experiments in salting butter, W. S. SWEETSER and R. J. WELD (*Pennsylvania Sta. Rpt. 1893, pp. 58–60*).—In 3 separate trials the churning was separated into 3 equal portions, 1 portion being salted at the rate of 1 oz. per pound, another at the rate of 1½ oz. per pound, and the third not salted. In one case only ½ oz. of salt was used instead of 1½ oz. In 2 of the churnings a fourth portion was salted in the churn by the use of a strong brine. The separate lots of butter were all worked as nearly alike as possible, and samples were taken for the determination of water, fat, and salt. The results of the trials, including the analyses of the butter, are tabulated. The butter salted with ½ oz. of salt contained 11.7 per cent of water; that salted with 1 oz. averaged 9.84 per cent; with 1½ oz., 9.68 per cent; salted with brine, 12.09 per cent; and unsalted, 13.31 per cent. "The amount of salt retained in the butter varied in these trials from 1.35 to 6.02 per cent and seems to be dependent upon the amount of salt added." When the butter was salted with brine "practically none of the salt was retained. . . . Salting by this method seems to be labor and salt thrown away."

The composition of dairy products, H. SNYDER (*Minnesota Sta. Rpt. 1893, pp. 50–62*).—A reprint from Bulletin 27 of the station (E. S. R., 4, p. 150).

Butter substitutes, W. FREAR, J. W. FIELDS, and W. S. SWEETSER (*Pennsylvania Sta. Rpt. 1893, pp. 55–58*).—Analyses are given of 5 samples of butter, 4 of which were found to be spurious. Remarks are also given on the interpretation of results of butter analysis, with compilations showing the average composition of butter.

An apparatus for airing and cooling fresh milk, B. BÖGGILD (*Mälkeritid., 7 (1894), pp. 717–721*).

Bacteria in their relation to the dairy, O. LUGGER (*Minnesota Sta. Rpt. 1893, pp. 259–290*).—A popular and quite comprehensive paper on bacteria and other micro-örganisms, their effect on milk and dairy products, sterilizing and pasteurizing milk, use of pure cultures in butter making, etc. The information appears to be wholly compiled.

The Colibri butyrometer (*Tidskr. Landtmän, 15 (1894), pp. 905–907; Nord. Mejeri Tidn., 9 (1894), p. 573*).—The apparatus, which is essentially a modified Babcock milk test, is manufactured at Stockholm; it is a hand machine, arranged for 20 bottles.

Warning against the use of preservatives for butter (*Tidskr. Landtmän, 15 (1894), pp. 915–918*).

TECHNOLOGY.

Grass-tree gum, J. H. MAIDEN (*Agl. Gaz. N. S. Wales, 5 (1894), No. 11, pp. 748–758*).—Notes on this resin, the species of *Xanthorrhœa* exuding it, its collection, and uses. *X. hastilis* exudes the resin most abundantly, but it is also secreted by *X. arboræ*, *X. australis*, *X. preissii*, and *X. tateana.* The gum varies in color from yellow to dark red, and also in consistency. It was used by the natives for fastening on the heads of spears, and is now used as a substitute for shellac and in candle making. It has also been employed medicinally in cases of dysentery. Experimental notes, analyses, and a bibliography of the subject are included.

On the quantity of wood gum (xylan) contained in different kinds of wood, J. OKUMURA (*College Agr. Bul., Tokyo, Japan, vol. 2, No. 2, pp. 76–78*).—Determination of the quantity of wood gum in 21 kinds of wood. "The Coniferæ are comparatively poor in wood gum and Ternstrœmia and Melia are also poor. Cupuliferæ are richer, Juglans, Magnolia, Cladrastis, Acanthopanax, etc., are still more so."

Essential oil of hops, A. C. CHAPMAN (*Jour. Chem. Soc. London, 1895, Jan., pp. 54–63*).

On certain changes in fats as they become rancid, A. SCALA (*Ann. Inst. Igien. Sper. (Roma), 6 (1894), pp. 353–362; abs. in Staz. Sper. Agr. Ital., 27 (1894), No. 4, pp. 424, 425*).—The fats investigated were butter, hog's lard, and olive oil. These were exposed to light and air and allowed to become rancid. The iodin numbers decreased constantly as rancidity advanced. To oleic acid rancidity was chiefly due. By oxidation it breaks up into similar compounds, liberating glycerin, which in turn is oxidized and transformed. As rancidity increases the ether numbers ascend, indicating the formation of aldehydes and oxy acids.

On the fat content of palm nuts, H. NÖRDLINGER (*Ztschr. angew. Chem., 1895, No. 1, pp. 19, 20*).

AGRICULTURAL ENGINEERING.

The ten-block system of numbering country houses, A. L. BANCROFT (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 173–186, figs. 28*).—An illustrated paper giving in detail an ingenious scheme for blocking off and numbering country roads and houses according to a decimal system. Samples of its successful operation are given and the method is summarized as follows:

"The roads of an entire county are arranged in as long lengths as practicable and are all named. They are then measured, commencing at the county seat or at the end nearest to it, and each mile is divided into 10 equal parts or imaginary blocks, having frontage only. Two numbers are assigned to each block; one to each frontage, the odd ones upon the left and the even ones upon the right—10 blocks to a mile; 20 numbers to a mile. Any house having an entrance in a block has the number of that block. The number for all but the first house in a block is followed by a distinguishing letter—742, 742*a*, 742*b*, etc. Divide the even numbers by 2 and point off one decimal, and the distance in miles and tenths from the commencement of the road is shown."

Irrigation and cultivation (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 343–348*).—A general discussion of the irrigation of orchards in central and northern California with special reference to peaches and prunes.

Fertilization in relation to irrigation, S. M. WOODBRIDGE (*California State Bd. Hort. Rpt. 1893 and 1894, pp. 315–318*).—A general discussion of the use of fertilizers and irrigation, insisting on the necessary connection of the two, and urging investigations in regard to the various amounts of water required for different crops.

Trials of plows at Storehedinge (Denmark), 1893, F. BOKELMANN, J. C. LA COUR, and H. F. K. DENCKER (*Tidsskr. Landökon. 12 (1894), pp. 745–802*).

Cultivation by means of steam plows, L. DANGER (*Landw. Wochenbl. Schles. Holst., 45 (1895), No. 1, pp. 5–9*).

History of tests of agricultural machinery in Denmark (*Tidsskr. Landökon. 12 (1894), pp. 737–744*).

STATISTICS.

Reports of director and of treasurer of Maine Station (*Maine Sta. Rpt. 1893, pp. 4, 7–9*).—The treasurer's report for the fiscal year ending June 30, 1893, and a brief general report on the work of the station by the director.

Annual Report of Minnesota Station for 1893 (*Minnesota Sta. Rpt. 1893, pp. 350*).—A brief review of the work of the year, list of the bulletins published by the station since its organization, treasurer's report for the fiscal year ending June 30, 1893, a reprint of Bulletins 26–32, with an index to the same, and an account of some hitherto unpublished investigations mentioned elsewhere.

Annual Report of Pennsylvania Station for 1893 (*Pennsylvania Sta. Rpt. 1893, pp. 7–13*).—This contains the treasurer's report for the fiscal year ending June 30, 1893, a brief review of the work of year by the director, and accounts of investigations noticed elsewhere.

Report of the statistician (*U. S. Dept. Agr., Division of Statistics Rpt. 122, pp. 705–778*).—The principal subjects treated are the following: Meteorological conditions of the year; crop review; statistics of the acreage, yield, and value in 1894 of the principal crops; farm prices December 1, 1894, of corn, wheat, rye, oats, barley, buckwheat, potatoes, sweet potatoes, hay, cotton, and tobacco; wholesale prices of corn, wheat, oats, barley, hay, cotton, butter, eggs, and tobacco in the principal cities in 1893 and 1894; statistics of agricultural exports and imports for 1893 and 1894; statistics of foreign crops; notes on foreign agriculture; and transportation rates. From the Abstract of the Eleventh Census of the United States tabular statements are compiled relative to the number, size, and value of farms; percentage of owned and rented farms; value of farm products per acre; and total value of land, improvements, machinery, and live stock in the different States.

MISCELLANEOUS.

Treatise on agriculture, A. ALOI (*Trattato di Agraria, vol. II, Agricultural. G. B. Paravia & Co., 1895, pp. 478*).

Advanced agriculture, H. J. WEBB (*London: Longmanns, Green & Co., 1894, pp. VI and 672*).

The education of gardeners, G. S. BOULGER (*Gard. Chron., 17 (1895), ser. 3, pp. 165, 166*).—To be continued.

Agricultural depression at home and abroad, W. E. BEAR (*Jour. Roy. Agl. Soc. England, 3d ser., 5 (1894), No. 20, pp. 673–695*).

The sale of cattle and the meat supply of Germany during 1891–'94, J. ARUP (*Tidsskr. Landökon. 13 (1894), pp. 685–708*).

The meat supply of England, 1893, J. ARUP (*Fifth Rpt. Danish State Agl. Councilors, 1893. Copenhagen: 1894, I–XIV*).

The conditions of North American competition in meat supply of England, N. HEYMAN (*Tidsskr. Landökon. 12 (1894), pp. 803–856*).

Agriculture in British Honduras (*Kew Misc. Bul. 97, pp. 9–11*).

Fifth Report of the Danish State Agricultural Councilors, 1893 (*Copenhagen: 1894, pp. 168*).

Annual Report of the Royal Danish Agricultural Society, 1893–'94 (*Copenhagen: 1894, pp. 180*).

Annual Report of the Royal Society for Norway's Weal for 1893 (*Christiania: 1894, pp. 102*).

Press bulletin excerpts (*Oklahoma Sta. Bul. 11, pp. 47–68*).—This is a summary of the more important articles furnished by the different departments of the station to the 15 press bulletins issued by the station since March, 1893.

NOTES.

CORNELL UNIVERSITY AND STATION.—A large room has been provided by the horticultural department to be used as a class room and museum, which will contain a collection of spraying apparatus, including every known device for spraying.

A law has been passed by the legislature of the State of New York appropriating $16,000 to be expended for horticulture in the fifth judicial department of the State, an area lying north and west of Cayuga Lake and including 16 counties. This fund is to be expended "in conducting investigations and experiments in horticulture; in discovering and remedying the diseases of plants, vines, and fruit trees; in ascertaining the best means of fertilizing vineyard, fruit, and garden plantations, and of making orchards, vineyards, and gardens prolific; in disseminating horticultural knowledge by means of lectures or otherwise, and in preparing and printing for free distribution the results of such investigations and experiments, and such other information as may be deemed desirable and profitable in promoting the horticultural interests of the State." All this work is to be prosecuted by Cornell University "under the general supervision and direction of the commissioner of agriculture." Agents and instructors are already in the field.

OHIO STATION.—A substation is being established at Strongsville, Cuyahoga County, on the heavy clay soil which characterizes a large portion of northeastern Ohio. It is intended to duplicate on this soil the experiments with fertilizers which are being conducted at the station at Wooster and at the substations at Columbus and in Fulton County.

PENNSYLVANIA STATION.—The burning of the State printing office at Harrisburg, February 9, destroyed the manuscript of the Report of the State College and the Experiment Station for 1894. The loss involves a large amount of labor and expense, as the report was to be an unusually elaborate and highly illustrated one. Work has already begun on its reproduction, but its distribution will necessarily be somewhat delayed, as none of the cuts were saved.

WASHINGTON COLLEGE.—The first annual winter school for farmers aroused much interest and enthusiasm among the farmers. The attendance represented 10 counties, and 303 were enrolled. The winter school will be made a permanent feature of the college work.

ANALYSIS OF SOILS AND ASH.—In conformity with the expressed desire of the Association of Official Agricultural Chemists at its last convention, that the availability of potash and phosphoric acid in soils should be made a subject of investigation during the present year, the "Directions for work on soil and ash samples" of the reporters on soils and ash recently issued provide, among other things, for the determination of the potash and phosphoric acid dissolved by digestion of the soil in 1 per cent citric acid for five hours with frequent thorough shaking; digestion for the same length of time in a solution of 6.3 gm. of oxalic acid in 1 liter of water; and digestion in the same manner in a solution containing 20 gm. of crystallized oxalate of ammonia and 2.15 gm. of anhydrous acetic acid. "The soils selected for study are from experimental fields that have been in cultivation as such for a series of years and the character of the soil is well known. One contains an abundance of available phosphoric acid, but not enough available potash, as shown by its responding to potash fertilizers in the field and not to phosphates. The other responds promptly to phosphates, and hence is probably deficient in available phosphoric acid. The plan is to demonstrate this difference by the action of solvents, and by selecting the solvent and method of treatment that is found to yield results in closest relation to the field results we will have the basis of a method for determining chemically the soil's needs."

PERSONAL MENTION.—Prof. R. Warington, the newly elected professor of rural economy of Oxford University, delivered his inaugural lecture February 4, the subject being the "Present relations of agricultural art and natural science."

Dr. A. Koch has been chosen professor of physiological botany in Göttingen.

○

EXPERIMENT STATION RECORD.

VOL. VI. No. 9.

At the last convention of the Association of Official Agricultural Chemists the abstract committee was requested to arrange for the periodical publication of their abstracts in the Experiment Station Record, the object being to make the abstracts more promptly available to the members of the association. This committee consists of five persons, and was first provided for at a meeting of the association in 1892. Its function is to prepare abstracts of current work on methods of analysis. Previous to that time a review of the work of the year had usually been furnished by the reporters on methods, each confining himself to his own special subject. It was expected that the abstract committee would not only relieve the reporters of this work but would also cover the ground more completely. The committee for 1894–'95 consists of W. Frear, of the Pennsylvania State College, chairman; W. D. Bigelow, of the Division of Chemistry of this Department; J. P. Street, of the New Jersey State Station; W. E. Stone, of Purdue University, Indiana; and R. H. Loughridge, of the University of California. This committee has arranged for the publication of its abstracts in the Record, and several abstracts have already appeared. The names of the members of the committee are attached to the abstracts prepared by them. It is hoped that by the coöperation of the association and the Division of Chemistry with this Office a quite complete survey of the work in agricultural chemistry now in progress throughout the world may be promptly presented to the readers of the Record.

In the present number of the Record Dr. Ewald Wollny begins a short series of articles in continuation of those published in volume 4, in which he will present a summarized statement of the results of investigations on the physical properties of soils. Renewed interest is being taken in soil investigations at home and abroad, especial prominence being given to studies of the physical properties and the bacteriology of soils. This is shown by the recent establishment of the Division of Agricultural Soils in this Department, which will give a very prominent place to studies of the physical properties of soils; by the investigation of the chemical composition and bacteriology of soils undertaken by the Division of Chemistry; and by the recent official announcement that the United States Geological Survey will broaden the scope of its work to include the nature and history of soil formations and the mapping of soil areas. As this subject is very complex, it is desirable that the various lines of investigation may before long be established on a thorough and permanent basis in different parts of the country through the coöperation of this Department, the experiment stations, and the agricultural colleges. There are three principal lines of investigation: The chemistry of the soil, in which a vast amount of data has been accumulated, for which there is at present no satisfactory interpretation, but in which there is yet important work to be done upon methods of chemical analysis and upon the form of combination in the soil; the bacteriology of the soil, which has hardly yet been placed upon a systematic basis; and the physical properties of soils. This last should include the texture and structure of soils and their relation to water and heat. The origin and the formation of the soils and their geological classification and areal mapping should be considered, as well as the effect of soil conditions, especially the amount of moisture existing in different types of soil or maintained by different methods of cultivation, upon the physiology of the plant. Meteorology should likewise be studied in all its bearings upon soil areas and different soil formations. A serious hindrance to the organization of a wide and thorough system of soil investigation in this country is the lack of instruction in this important subject in our colleges, and of properly trained experts to carry out the details of the work. Opportunities are open now for a considerable number of workers in these lines. In view of these facts more attention should be paid to those branches which have a direct bearing upon original research in soils, and several centers of instruction should be established in certain sections of the country, presided over by men who are authorities on soil studies and who are themselves carrying on important soil investigations. It is important, in the first place, that a well-considered and systematic course of instruction bearing upon soil investigations should be presented at these institutions. The special line of research should depend partly upon the environment and condition of the institution. Different portions of our country offer exceptional advantages for work in one or more of these lines. The physical and physiological problems can best be studied in the arid regions where irrigation is practiced and the water supply can be controlled. In the Middle and Southern Atlantic and Gulf States suitable material for inquiries on the geologic problems is found in the wide number of distinctly typical soil conditions there represented. In the glaciated area none of these problems can be so well investigated, but chemical and bacteriological studies of soils can be as well carried on there as elsewhere. Specialization will count for as much here as elsewhere, and it will be far better that only a few well-equipped institutions should undertake this work and stake their reputation largely upon it. Great soil areas and great agricultural conditions must be considered, rather than interests bounded by State lines.

THE PHYSICAL PROPERTIES OF THE SOIL.

Dr. EWALD WOLLNY.

PART 1.

Having already shown[1] the significance of the physical properties of the soil in the growth of plants, I shall attempt in the following pages to set forth briefly, in the light of investigations made up to the present time, the nature of these properties and the corresponding differences among soils of different kinds under varying external conditions.

I.—THE PRINCIPAL SOIL CONSTITUENTS.

We may regard quartz, lime, clay, and humus as the principal constituents of the soil which influence its texture or mechanical character, and hence its behavior toward water, air, and heat, although under certain conditions a similar influence may be exercised by iron compounds and certain salts. In so far as the character of the mass depends on the size of its component particles, the constituents may be divided into sand (fine and coarse), finer particles which can be easily washed away (silt) and humus. The fact that these substances have very different properties, and occur in widely varying proportions, explains the marked differences that exist in the physical properties of natural soils, and a knowledge of the principal peculiarities of these individual constituents, and of their mutual relations, as well as of the proportions in which they are present in any particular instance, is therefore of primary interest and importance.

II.—GENERAL PHYSICAL PROPERTIES OF THE SOIL CONSTITUENTS AND OF THE SOIL AS A WHOLE.

THE SIZE OF THE SOIL PARTICLES.

The size of the soil particles varies within wide limits. In plastic clays the size of the grains is between 0.0001 and 0.005 mm.;[2] in the coarsest kinds of sand they are as high as 2 mm. in diameter. The extreme variation is therefore between 0.0001 and 2.0 mm. That part of the soil consisting of particles 2 to 5 mm. in diameter is called gravel, 5 to 10 mm. coarse gravel, and above 10 mm. stones. The portion made up of particles over 0.25 mm. in diameter is termed the "soil skeleton," that of finer grains the "fine earth." According to the preponderant size of the grains we distinguish between gravelly, sandy, coarse-grained, fine-grained, and dusty soils.

---

[1] E. S. R., 4, pp. 528, 627.

[2] M. Whitney, U. S. Dept. Agr., Weather Bureau Bul. 4.

THE FORM OF THE SOIL PARTICLES.

This is generally very variable. The finest particles of clay are long and rounded, and rather uniform in shape; in sands the grains are frequently more or less cubical. Most of the other soil elements are of angular and irregular form.

Molecular constitution of the soil particles.—All particles of mineral origin are either crystalline or amorphous. In the former, and to a certain extent in the latter case, they are nearly or quite impermeable to water and gases. Some of the amorphous constituents have the properties common to colloid substances of swelling up in presence of water and forming a sort of jelly, and of returning to their original condition on drying. Examples of such colloid substances are the plastic constituents of clay, the amorphous zeolitic silicates, ferric oxid, silicic acid in certain conditions, and humus. These materials, although to a considerable extent hypothetical, are of great significance in the study of the physical and chemical properties of the soil. Upon them depends the plasticity of clay soils. Decaying plant remains render soils more porous and hence more permeable to gases and liquids.

Determination of the size of the particles (mechanical analysis), and of the soil constituents.—Mechanical analysis of soils, by means of sieves, or by elutriation, consists in the separation of the soil into portions of varying coarseness, and the quantitative determination of the proportions of these different grades. In this way the soil may be separated into the following products:

Grades obtained in mechanical analysis of soils.

Soil skeleton..	(1) Over 10 mm. diameter	stones.
	(2) 10 to 5 mm. diameter	coarse gravel.
	(3) 5 to 2 mm. diameter	medium gravel.
	(4) 2 to 1 mm. diameter	fine gravel.
	(5) 1 to 0.5 mm. diameter	coarse sand.
	(6) 0.5 to 0.25 mm. diameter	medium sand.
Fine earth....	(7) 0.25 to 0.1 mm. diameter	fine sand.
	(8) 0.1 to 0.05 mm. diameter	coarse silt.
	(9) 0.05 to 0.025 mm. diameter	medium fine silt.
	(10) 0.025 to 0.005 mm. diameter	fine silt.
	(11) 0.005 to 0.0001 mm. diameter	colloid clay.

Grades 1 to 5 are separated by sieves with circular holes, grades 7 to 11 by elutriation.

In preparing a sample of soil for analysis care must be taken that the coarser materials are freed from finer particles, and that all lumps are broken up. This is effected by boiling for 10 to 20 hours with distilled water.[1] The sample so treated is washed through a sieve with round holes by means of distilled water, using a brush if necessary.

Elutriation may be carried out in two ways. One of these depends on the subsidence of solid bodies in water and may be called the decantation or hydrostatic method (Davy, Schübler, Sprengel, Benningsen-Förder, Knop, Schlösing, Kühn, Osborne, Fadejeff). The other depends on the force of upward flowing water, or hydraulic pressure, and is called the hydrodynamic method (Nöbel, Schöne, A. Mayer, Hilgard). Of the modifications of the first or hydrostatic method, Kühn's is preferable for ordinary work on account of its simplicity; Fadejeff's method, however, gives more exact and more closely agreeing results. Of the hydrodynamic methods, those using a conical washing vessel (Nöbel, Schöne, A. Mayer) give unsatisfactory results, on account of the backward currents along the sides of the vessel, which produce flocculent aggregates of the smaller grains which sink to the bottom and remain with the coarser sand. To avoid this difficulty Hilgard uses a vertical cylindrical tube and an agitating apparatus the object of which is to destroy any floccules that may be formed. Hilgard's apparatus may be regarded as the most satisfactory, at least for particles less than 0.1 mm. (8 mm. hydraulic value), which has yet been devised.[1]

---

[1] E. W. Hilgard, Forsch. Geb. agr. Phys., 2, p. 57.

In carrying out mechanical soil analysis of any kind various precautions must be observed in order to insure accuracy. Besides the 10 to 20 hours' brisk boiling of the sample which is essential, water as pure as possible (distilled) must be used in the elutriation, because in water containing salts floccules are apt to form which settle and remain with the coarser ingredients. For the same reason the apparatus must be protected from all variations of temperature and from strong light. It is therefore best placed in a dark cellar which is subject to only slight variations in temperature. For the accurate separation of sediments of definite hydraulic value the elutriation must be preceded by the removal of the clay, as otherwise the heavy, clayey water, having a high hydraulic value, will carry away larger particles than correspond to the real velocity of the water. The other particles may be separated from the clay by repeated sedimentation in a column of water 20 cm. deep for periods of 24 hours.[2]

The separation of soil into the above-mentioned portions furnishes a basis for interpretation of those physical properties which depend upon the size of the soil particles, but throws no light on the influence in this respect of colloid and humus substances. Colloid clay[3] is the most important of the former class, for to it is due the property of plasticity. Kaolin particles occur in the soil, but they behave like any other mechanical constituent, and are no more plastic than chalk or fine siliceous earth. For the determination of "active" clay the method of Hilgard just mentioned, or that of T. Schlösing, may be used.[1] The clay sediment, however, may contain fine particles of other substances besides clay, such as quartz, ferric hydrate, etc., and it may be necessary to determine these chemically and subtract the weight of these from the total weight of the sediment.

[2] E. W. Hilgard, Forsch. Geb. agr. Phys., 6, p. 53.

[3] M. Whitney and others have recently ascribed the properties of colloid clay and other similarly constituted substances to the extreme fineness of their particles, and hence the very much greater attraction the latter can exert compared with any substances made up of comparatively coarse grains.

The humus substances are also determined chemically, especially the colloid humus matter (*matière noire*) which is physically very important. This determination is best made by Grandeau's method.[2]

When the constituents themselves are considered in their relation to the properties of the soil, aside from the effect due simply to the size of the particles, as for instance with reference to the conduction of heat, chemical analysis can not be dispensed with, for mechanical examination can not give the necessary information.[3] Under certain circumstances it may be of importance to make an examination of the mineral constituents of the different sediments.[4]

THE ARRANGEMENT OF THE SOIL PARTICLES (STRUCTURE OF THE SOIL).

Separate grain structure.—If we consider a soil divided up into its individual particles, which are massed together more or less closely, we see that the size of the interstitial spaces and consequently the movement of water and air in the soil are dependent solely on the size and form of the particles. This arrangement is called (after Hilgard) the "separate grain structure" (*Einzelkornstructur*). If the particles are spherical and of equal size they can be supposed to be massed together in either of two ways: (1) Each sphere rests in the space between the adjoining spheres (Fig. 4), or (2) the planes tangents to the spheres at all their points of contact intersect at right angles. The former arrangement produces a three sided or four sided regular pyramid while the latter gives rise to a cubical form (Fig. 5). In the first case the arrangement is the most compact possible and the volume of the intergranular space (volume of pores) amounts to 25.95 per cent of the total volume. In the second case we have the least compact arrangement, and the volume of the pores rises to 47.64 per cent of the total

[4] F. Steinriede, Anleitung zur mineralogischen Bodenanalyse, 1889.

volume.[1] The volume actually occupied by the solid particles is independent of the size of the spheres, in both the above cases, so long as all the spheres in the mass are the same size.[2]

In ordinary arable soils the conditions are somewhat different, due to the fact that the particles are not spherical and are of different sizes, and that external conditions exercise a considerable influence on the structure. The arrangement may be more compact than in the first case described above on account of the smaller grains depositing themselves in the spaces between the larger ones (Fig. 6), or may be less compact than in the second when the particles arrange themselves as in Fig. 7. Shaking and packing increase the density of the soil, but this is principally caused, and to the greatest extent, by the percolation of water, which acts mechanically on the soil (puddling it).

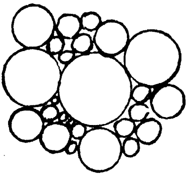

FIG. 6.

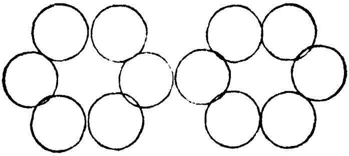

FIG. 7.

The volume actually occupied by soil particles is smallest, relatively, in soils containing porous fragments, especially those rich in humus (peat).

From what has been said it is not surprising that the volume of the pores, which depends on the arrangement of the particles, varies within wide limits in natural soils. According to the experiments made on this subject by C. Flügge[3] the volume varies in mineral soils between 20 and 57.8 per cent, while in peat and moor soils it may rise to 85.2 per cent, according to E. Ramann and A. R. von Schwarz.[4]

Crumbly structure.—In many soils aggregates or floccules are formed under certain circumstances. This kind of arrangement differs from that already described principally in the occurrence of a considerable number of larger spaces between the aggregates, owing to the virtually larger size of the particles. These larger spaces bring about very important differences in the physical properties of the soil, especially in its behavior toward water and air. This kind of arrangement of the soil particles is shown in Fig. 8.

There are various reasons for the formation of aggregates. The tendency is approximately inversely proportional to the size of the particles concerned, and ceases for the most part in quartz powder when the diameter of the grains rises to 0.2 mm., supposing all the particles to be of the same size, for particles larger than 0.2 mm. diameter may enter into aggregates made up for the most part of smaller grains. The number of grains which can cohere in this way varies also in approximately the same manner. The larger the individual grains the more easily their aggregates fall to pieces. The occurrence of sediments of the same hydraulic value but of different specific gravity show that a higher density tends to diminish flocculation. This tendency also decreases rapidly with an increase in temperature, being very weak in water near its boiling point.[1] Colloid substances are also very influential in the formation of floccules, and the free insoluble humus acids produce the same result by binding the other constituents together.[2] The formation of aggregates is greatest when the soil contains a medium quantity of water, *i. e.*, about 40 per cent of the maximum quantity which it is capable of holding, and a greater or less quantity of water always diminishes the tendency toward flocculation.[3]

[4] Forsch. Geb. agr. Phys., 2, p. 164.

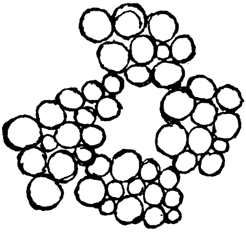

FIG 8.

Of secondary importance is the fact that the soluble salts of the soil, even when present in very small quantities, exert an important influence on its structure.[4] Caustic alkalies (potash, soda, and ammonia), as well as their carbonates and phosphates, cause a compact arrangement of the individual grains, and hinder or prevent the formation of aggregates, while the mineral acids (hydrochloric, sulphuirc, and nitric) and their salts, with the exception of the neutral alkaline sulphates, which rather approach the preceding group in behavior, materially aid flocculation. In the case of the chlorids and nitrates this is true only while they remain in the soil liquids. When they are washed out by the atmospheric water, which readily takes place, a more compact arrangement of the individual atoms results. Calcium hydrate (caustic lime) and, to a less extent, calcium carbonate help to form light, loose aggregates, which resist external influences tending toward their disintegration for a longer or shorter time, according to the quantity of the flocculating substance present.

Among external factors which influence the structure of the soil frost is of first importance. By the freezing and consequent expansion of the water the particles are torn apart. In a compact soil having a tendency to form floccules frost will, as a rule, bring about a crumbly structure, while in a soil already mechanically finely divided the particles will be either so far separated as to cause the formation of the "separate grain" structure, or may be more closely consolidated by the action of frost.

Destruction of the crumbly structure is promoted by violent shaking with water, kneading, and boiling of the mass. These means, as is well known, are used in pottery work to increase the plasticity of the clay, the object being to break up aggregates of particles as completely as possible.

Atmospheric water exerts a decided influence on the structure of the soil by altering the position of the soil particles and also by carrying the smaller grains downward. The crumbly structure of the soil is destroyed more or less by the percolating water, which loosens particles from the fragments and washes them into the larger spaces, and this takes places in proportion to the quantity of the percolating water and the lack of tendency toward flocculation in the soil. The greater the force of the falling water the sooner the soil assumes the separate grain structure, and therefore violent thunderstorms may entirely change the mechanical condition of the soil in a short time. From such facts we may infer that the frequency of atmospheric precipitation, other things being equal, exercises a great influence on the structure of the soil. Frequent light rainfalls have much less effect than violent storms at longer intervals.

Covering the soil with living or dead plants lessens the mechanical effect of atmospheric precipitation by breaking the force of the falling water and retarding its penetration into the soil, and this influence of plant cover varies with its compactness and state of development. If the ground is covered with straw, the compacting of the soil by rain will diminish as the thickness of the covering increases.[1]

Structural changes in the soil may also be caused by the washing away of the surface particles on sloping land by the water that does not sink into the soil (erosion). In the case of leaching, the washing of the smaller particles into the subsoil increases with the differences in the size of the particles; in the case of erosion the washing away of the finer-grained constituents is greater the less compact the soil, the greater the slope, and the heavier the rainfall. In both cases change in position of the soil particles is prevented to a great extent by a covering of living plants whose roots hold the soil together. Forest growth has a stronger retarding action than that of perennial herbs.

The wind transports the finer particles of dusty soils in proportion to its strength. The places from which the material has been blown necessarily have a coarser soil structure than those composed of the deposited dust.[2]

Finally, the animal life of the soil exerts an important influence on the formation of aggregates. This is especially true of the ordinary earthworm, whose digging, burrowing, and excretions are important agencies in the formation of vegetable mold.[1]

CHANGES IN VOLUME OF THE SOIL.

Variations in the volume of soils are shown by changes in the space occupied when different quantities of moisture are present. These changes are most marked in soils which contain much colloid material (clay, and especially humus matter), while in sands they are not observed, or only to a slight extent in very fine sands. In the latter case the expansion is due solely to the surrounding of particles by water when the soil is very wet.[2]

In clays and clayey soils the changes in volume consequent on drying cause a vertical and especially a horizontal tension in the mass. Loss of water at the surface of the soil causes a contraction of the uppermost layer and a consequent strain from below upward, reaching to a depth dependent upon the depth of the surface drying. Under such circumstances the soil must become more closely compacted and the surface sink to a lower level. These changes in volume often cause cracking of the soil, chiefly due to the horizontal tension already mentioned. This separation of the soil particles will decrease as the force increases which holds the particles together, that is, as the cohesion of the soil increases (see below). Experience teaches, however, that even the most tenacious soils have not sufficient resistance to prevent the formation of cracks by lateral tension when drying proceeds to a considerable extent. It is plain that this tension is not uniform either at the surface or below because the drying and the consequent contraction goes on more quickly in some parts of the soil than in others. The top layers dry soonest and most completely and therefore contract more strongly than the lower and moister strata. The cracks formed, then, will be widest at the top and will become narrower on descending.[3]

The cracks formed in the same soil by drying are deeper, narrower, and less numerous the more compactly the particles are arranged, and *vice versa*.[4]

Expansion and contraction of the soil are also observed in freezing and thawing, and the greater the quantity of water in the soil the more marked are the changes in volume due to this cause, being especially marked in soils rich in humus and clay.

[4] E. Wollny, Forsch. Geb. agr. Phys., 5, p. 43.

THE COHESION OF THE SOIL.

Cohesion is the force with which soil particles adhere to one another. As a measure of this we may use the resistance which the soil opposes to a separation by tension (relative firmness) or pressure (absolute firmness), or to the penetration of a wedge-shaped body (resistance to separation). Cohesion depends on the mechanical constitution and the humidity of the soil as well as on the presence of different salts. Of the soil constituents clay possesses the greatest cohesive power, while the particles of quartz, humus, and lime are comparatively weak in this respect. The cohesion of a soil, therefore, increases with the quantity of clay it contains and diminishes as the quantity of quartz, humus, or lime increases. Under otherwise similar conditions the attraction between the soil particles is greatest when the particles are smallest. It also depends on their arrangement. Soils with separate grain structure, other conditions being the same, have a higher cohesion than crumbly soils. By pressure the cohesion is increased in proportion to the force acting. The influence of water is apparent in the fact that in clays and soils rich in clay the cohesion is greatest when the quantity of water present is least, while in humus, quartz, and chalk the constituents of the soil cohere most strongly when a definite proportion of water is present, either more or less than this quantity causing a decrease in cohesion. The freezing of water in the soil causes a remarkable increase in the resistance offered to the penetration of a wedge-shaped body (resistance to separation), and also to forces tending to break up the mass (absolute firmness). By mixing caustic lime with clay the firmness of the latter is considerably diminished for all states of moisture, while potassium hydrate or alkaline carbonates increase the cohesion in the dry state and seem to decrease it when the mass is very moist. Other conditions being equal, the resistance to the entrance of wedge-shaped bodies is much greater when the soil is covered with plants than when bare.[1]

THE ADHESION OF THE SOIL.

This property is apparent in the fact that the soil adheres to a greater or less extent to the wood and iron parts of agricultural implements. From the investigations on this subject, it appears that a number of circumstances seem to influence the force which causes adhesion.[2] It is proportional to the surface in contact and increases with the amount and duration of pressure.

In sandy soils (quartz and calcareous sand) adhesion is greater the smaller the particles; in powdery soils (separate grain structure) adhesion is considerably higher than in the same soil in a crumbly condition. Of the different soil constituents, clay shows the strongest adhesion to wood and iron and humus the weakest, while quartz is intermediate. The soil, therefore, adheres to the implements most strongly when it is rich in clay and less strongly when quartz and humus predominate. The influence of water varies in differently constituted soils. In sandy soils adhesion increases with an increase of water up to complete saturation. In soils rich in clay adhesion to wood and iron reaches a maximum at a definite humidity (80 per cent of the quantity required for saturation), below and above which adhesion decreases. Humus seems to act like quartz, in respect to the influence of moisture. In the dry state, adhesion in all kinds of soils is zero.

---

[1] W. Schumacher, l. c., p. 125. G. Schübler, l. c., p. 74. F. Haberlandt, Wissenschaftlich-practische Untersuchungen auf dem Gebiete des Pflanzenbaues, 1875, vol. 1, p. 22; Forsch. Geb. agr. Phys., 1, p. 148. H. Puchner, Ibid., 12, p. 195.

[2] G. Schübler, l. c., p. 76. F. Haberlandt, Der allgemeine landwirthschaftliche Pflanzenbau, 1879, p. 393. F. Schachbasian, Forsch. Geb. agr. Phys., 13, p. 193.

The addition of caustic lime has no appreciable effect on the adhesion of soil to agricultural implements, but caustic alkalies seem to cause a firmer adhesion of clay.

Clayey soils adhere to wood more firmly than to iron, while with soils rich in quartz and humus the reverse is true. Adhesion of soils to rusty iron is almost invariably less than to polished iron, and in case of soils rich in clay, less than to wood. Only in soils containing much quartz are the adhesive values greater for rusty iron than for wood.

THE FRICTION OF SOILS ON WOOD AND IRON.

The resistance which is offered by friction to the sliding of implements over the soil is expressed by the ratio of the force which is necessary to overcome the resistance to friction to the weight of the moving or sliding body (coefficient of friction). This coefficient varies, according to the nature of the materials concerned, between 0.33 and 0.82. Other properties being the same, fine-grained soils show a greater resistance when moist than when dry. If the soil is moist, the resistance offered to wooden and iron implements is greater when the soil has the separate grain structure than when it is crumbly, but if the earth is dry the reverse is true. As regards the behavior of the various soil constituents, experiments[1] show that the coefficient of friction is greatest in quartz sand or calcareous sand, and smallest in clay, while humus possesses an intermediate value. The coefficient of friction diminishes with the quantity of moisture in the soil, and is greater for wood than for iron. Rust increases considerably the coefficient of friction for iron.

THE SPECIFIC GRAVITY OF THE SOIL.

This is the ratio of the weight of the soil to that of an equal volume of water considered as unity. For different soil constituents the following values have been found (E. Wollny):

---

[1] F. Schachbasian, Forsch. Geb. agr. Phys., 13, p. 214.

Specific gravity of soil constituents.

Quartz	2.622
Clay	2.503
Lime, carbonate crystalline	2.756
Lime, carbonate precipitated	2.678
Gypsum, precipitated	2.318
Oxid of iron	4.54–5.20
Hydrated oxid of iron	3.760
Humus	1.462

With these values it is possible to calculate the density of any soil.

The more important minerals occurring in soil have the following specific gravities:[1]

Specific gravity of different minerals.

Feldspar	2.5 to 2.8	Calcite	2.6 to 2.8
Orthoclase	2.5 to 2.6	Dolomite	2.8 to 3.0
Oligoclase	2.6 to 2.7	Chlorite	2.7 to 3.0
Labradorite	2.6 to 2.8	Talc	2.6 to 2.7
Augite	3.2 to 3.5	Magnetite	4.9 to 5.2
Hornblende	2.9 to 3.4	Limonite	3.4 to 4.0
Mica	2.8 to 3.2	Hematite	5.1 to 5.2
Potash mica	2.8 to 3.0		
Magnesia mica	2.8 to 3.2		

THE VOLUME WEIGHT OF THE SOIL.

This is also called apparent specific gravity, and is the weight of a given volume of the soil compared with an equal volume of water. In the specific gravity we are concerned only with the volume of the actual solid matter of the soil, exclusive of the air or water that occurs in the spaces between the particles; in the volume weight we consider the soil as a whole, including the spaces occurring in it.

According to the investigations of the author[2] quartz has the highest volume weight in the air-dry state (1.4485), humus the lowest (0.3349), and clay a value intermediate between the two (1.0108). The volume weight of soils, other things being equal, increases with the presence of iron and stones. The volume weight of one and the same soil depends on the mode of arrangement of the particles and is subject to great variations. The more compactly the particles are arranged the greater is the weight of the mass, when equal volumes are considered, and *vice versa*. Under otherwise similar circumstances the coarser the grains the higher the volume weight. A mixture of grains of different sizes has a higher volume weight than a mass composed of grains of the same size, large or small. By the formation of floccules in a soil, its volume weight is decreased in proportion to the coarseness of the aggregates formed.

---

[1] G. Schübler, Grundsätze der Agriculturchemie, 1838, pt. II, p. 61. C. Trommer, Die Bodenkunde, 1857, p. 258. A. von Liebenberg, Ueber das Verhalten des Wassers im Boden, Inaugural-Dissertation, Halle, 1873. C. Lang, Forsch. Geb. agr. Phys., 1, p. 136. G. Ammon, Ibid., 2, p. 26. E. Wollny, Ibid., 8, p. 347. E. Ramann, Forstliche Bodenkunde, 1893, p. 61.

[2] Forsch. Geb. agr. Phys., 8, p. 349.

With regard to the influence of water, experiments have shown that the volume weight of soils increases with the water content, and the increase is proportional to the water capacity of the soil. The differences in volume weight correspond, in general, when soils are approximately equally saturated, to those in air-dry soils, though the values are more concordant in moist soils.

The expressions "heavy" and "light" soils, used in practice, have no reference to the weight of the mass, but to the resistance which the soil opposes to cultivation.

It is sometimes advisable to examine the soil in its natural state on account of the not inconsiderable variations in the volume weight. This is most conveniently done by lifting out a column of the soil by means of a sampling tube which is driven to a definite depth in the earth and drying and weighing the sample.[1]

THE COLOR OF THE SOIL.

This is due to the presence of certain constituents. The principal mineral ingredients of the soil (clay, lime, and quartz) are white when pure. When the soil is of some other color it is caused by the presence of humus matter or iron compounds. The humus substances produce a gray, brown, or black color, according to the quantity present, while iron, as ferric oxid or hydrate, causes a yellow, brownish, or red color. The coloring power of these constituents depends on the constitution of the soil. In sands 0.2 to 0.3 per cent of humus materials or 1 per cent of ferric oxid or hydrate suffice to cause either a gray or a red or brown coloration in the dry state, but in clays more (2 to 5 per cent humus, 5 to 10 per cent ferric oxid or hydrate) is required to produce the same effect. This is due, as a rule, to more intimate mixture of the clayey soils with the coloring matters. A green coloration is almost without exception caused by ferrous compounds, and is seldom noticed in well aërated soils.

A change in color in a soil is caused on the one hand by a change in humidity, on the other by a change in the iron compounds. In general, soils are darker colored when they contain more water, and *vice versa*. This is especially true of soils containing much humus, which are dark brown or black when wet, become lighter as the moisture decreases, and when dry show a gray or whitish-gray color. Soils colored red or brown by ferric oxid or hydrate assume a lighter color and under certain circumstances (deficiency of air) a greenish color when these compounds are converted into ferrous compounds. The reverse process, *i. e.*, the oxidation of ferrous salts, is shown by an immediate change in the color of the mass to yellow, red, or brown.[2]

[2] W. Schumacher, Die Physik des Bodens, 1864, p. 139. E. Ramann, Forstliche Bodenkunde, 1893, p. 36. E. Wollny, Forsch. Geb. agr. Phys., 4, p. 354.

THE STRATIFICATION OF THE SOIL.

The soil, as a whole, is by no means uniform, and this is especially true of sedimentary soils. Different soil layers have a different mechanical constitution, the difference being sometimes very great. Since the individual layers behave differently toward water, air, and heat, the determination of the arrangement of these layers is of particular importance. The stratification may be ascertained by the examination of vertical sections of soil exposed in pits dug at various suitable places or on the surface of columns of soil taken by means of a sampling tube. Information can also be obtained as to stratification of the soil by examining existing exposures, such as railroad and other cuts and excavations.

The upper layer of the soil, containing the roots of plants and altered by vegetable growth, is called "surface soil," while the layer below this is termed "subsoil." The surface soil includes two layers, an upper one or tilled soil, which is artificially altered by tillage, and a lower one influenced only by the growth of plants, and otherwise in its natural condition. We may therefore distinguish between an upper and a lower surface soil. In practical agriculture the term surface soil generally indicates only the upper layer or tilled soil, while the subsoil means the part of the soil below this. The subsoil here begins immediately below the tilled soil, no matter how thick or how thin this may be. The subsoil is sometimes regarded as that layer on whose texture the moisture of the upper layer depends (permeable or impermeable subsoil). A consistent and general terminology does not exist at present, but that suggested above corresponds best with natural conditions.[1]

THE DEPTH OF THE SOIL.

The depth of the soil means the thickness of that part which can be penetrated by the roots of plants. This is of great importance to crops, inasmuch as, within certain limits, they develop proportionately to the thickness of the layer in which they can extend their roots. The depth of the soil, therefore, is determined by the distance below the surface of the layer which prevents the growth of the subterranean organs of the plant. In mountainous districts the depth of the rock below the surface determines the depth of the soil. In level lands the depth of the soil is determined by the distance below the surface of layers of closely compacted materials (clay, rock, bog-iron ore) or of coarse gravel or sand, which prevent more or less completely the growth of the roots on account of their impenetrability, excess of water, or deficiency in the substance necessary to the life of the organs. With regard to the depth of different soils the following gradations may be noticed:

Thin soil	15 to 30 cm.
Medium soil	30 to 60 cm.
Thick soil	60 to 100 cm.
Very thick soil	above 1 meter.

---

[1] L. von Liburnan, Die geologischen Verhältnisse von Grund und Boden, 1883, p. 223. A. Nowacki, Practische Bodenkunde, 1892, p. 39. F. Dafert, Kleines Lehrbuch der Bodenkunde, 1885, p. 162. W. Schumacher, l. c., p. 326.

THE POSITION OF THE SOIL.

The surface of the soil is either horizontal or inclined; in the latter case the slope may be uniform or nonuniform, and vary in regard to the points of the compass and in respect to the horizontal. The compass direction is called the "exposure," the slant in respect to the horizontal is the "inclination."

The exposure may be easterly, southerly, westerly, northerly, or may have some intermediate direction. With regard to varying inclination we have the following gradations:

Level or slightly sloping	0 to 5° to the horizontal.
Sloping	5 to 10°.
Very sloping	10 to 20°.
Steep	20 to 30°.
Very steep	30 to 45°.
Precipitous	above 45°.

The exposure and the inclination are of great importance in many ways, because upon them depend the conditions of warmth and humidity of the culture layer, and also of erosion of the soil. The former consideration determines the choice of crop and the latter the possibility of cultivation.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Comparison of methods of sugar analysis as applied to grape juice (musts), G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 326, 327*).—A comparison is given on 3 samples of grape juice of the volumetric and gravimetric methods described in the Proceedings of the Association of Official Agricultural Chemists for 1892.[1] The results by the volumetric method and the electrolytic gravimetric method agreed quite closely, but the method of reducing the cuprous oxid in hydrogen gave results somewhat higher.

The unreliability of the Kjeldahl method for determining nitrogen in chloroplatinates, DELEPINE (*Bul. Soc. Chim. Paris, 13–14 (1895), No. 4, p. 222*).—Trials of this method on chloroplatinate of trimethylamin gave results in no way approaching the theoretical percentages of nitrogen. This was due to the escape of free nitrogen.

Researches on the separation of free hydrochloric acid from chlorids, especially in analysis of the gastric juice, H. LESCŒUR (*Bul. Soc. Chim. Paris, 13–14 (1895), No. 3, pp. 142-155, fig. 1*).

The transformation of starch into sugar, DUCLAUX (*Ann. Inst. Pasteur, 9 (1895), No. 1, pp. 56–64*).—A critical review.

Rapid determination of starch, P. L. HIBBARD (*Neue Ztschr. Rübenz. Ind., 34 (1895), No. 7, pp. 86, 87*).

The action of ammonia upon dextrose, W. E. STONE (*Amer. Chem. Jour., 17 (1895), No. 3, pp. 191–196*).

The carbohydrates of the gum of Acacia decurrens, W. E. STONE (*Amer. Chem. Jour., 17 (1895), No. 3, pp. 196–199*).—This gum "does not essentially differ from gum arabic or peach gum or cherry gum. It furnishes an additional example of the occurrence of a galacto-araban complex."

On the composition and analysis of brandy, X. ROCQUES (*Compt. Rend., 120 (1895), No. 7, pp. 372–374*).

The oxidation of tannin in cider, L. LINDET (*Compt. Rend., 120 (1895), No. 7, pp. 370–372*).—It is claimed, as pointed out by Bertrand (*Compt. Rend., 120 (1895), No. 5, p. 266*), that the brown coloration of the cider and marc is due to the energetic oxidation of the tannin present by a ferment similar to diastase which is designated *laccase*.

The determination of tannin in wines, A. VIGNA (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 19–22*).

On the analysis of tannin compounds, A. GIRARD (*Compt. Rend., 120 (1895), No. 7, pp. 358–360*).—The discordant results obtained by different chemists with the author's method (*Compt. Rend., 95 (1892), p. 185*), are explained by variations in the character of the intestinal membrane used. The difficulty is removed by carefully purifying the membrane.

BOTANY.

The method and application of a quantitative botanical analysis of meadows, A. VOIGT (*Landw. Jahrb., 23 (1894), No. 4 and 5, pp. 707–788, figs. 2*).—The author reviews the methods heretofore employed in making botanical analyses of meadows, and points out some of their deficiencies. The value of botanical analyses as compared with chemical analyses is shown. Chemical analysis of grasses does not always represent the true value of meadows either for pasturage or hay as well as a botanical analysis, as from the latter may be seen the relative value of various species, based on the avidity with which stock will eat them.

The method suggested by the author for securing representative material for a quantitative botanical analysis of an area of 1 are is as follows: Immediately after mowing from each swath at distances of about 50 cm., specimens are taken in proportion to the size and abundance of the material. This forms what is called type 1, and will weigh from 17 to 30 kg., depending on the abundance of the material. This type is then spread about in a circle of 1.5 to 2 meters in diameter until it is of a uniform thickness and of apparent homogeneity. From this circle type 2 is taken, by removing a handful at a time from different parts of the circle until about one fourth of the total quantity is secured. This type is similarly treated to secure types 3 and 4, the final one of which will weigh from 2 to 4 kg. From this last so-called type the botanical determinations are made, a part being retained for control analysis. When strong plants, as thistles, meadow sweet, etc., are present, they must be broken up, so as to permit of a more even distribution of their material. The principal difficulty in such an analysis will be with the grass leaves, such as are found in aftermath. These must be removed, assorted, weighed, and their proportion to the whole ascertained. Their determination is difficult, and should be made by a specialist. The same is true of the sedges, mosses, etc. In this way the species of plants found in a meadow and their relative abundance may be determined with reasonable accuracy.

The author divides the more common grasses into 4 categories, the groups and species being arranged according to their relative value for forage, the first being considered the best, the others decreasing in value according to their position in the list. Group 1, ***Festuca elatior, Lolium perenne, Dactylis glomerata, Arrhenatherum elatius, Avena flavescens, Phleum pratense, Poa pratensis, P. trivialis, Agrostis alba, Glyceria fluitans, G. aquatica,*** and ***Cynosurus cristatus.*** Group 2, ***Festuca rubra,*** *Anthoxanthum odoratum*, *Agrostis vulgaris*, *Briza media*, and *Alopecurus geniculatus*. Group 3, *Holcus lanatus*, *H. mollis*, *Bromus mollis*, *Agrostis canina*, and *Festuca ovina*. Group 4, *Molinia cœrulea*, *Aira cæspitosa*, *A. flexuosa*, *Sielingia decumbens*, *Nardus stricta*, and *Phragmites communis*.

The author has repeatedly tried the above method and considers it much more reliable than any other. The practical application of such an analysis the author considers under 6 heads: (1) Influence of fertilizers and differences between first and second cuttings; (2) a knowledge of the local differences in meadows as bearing on ameliorating conditions; (3) ability of different species to form aftermath, and variations in the same; (4) classification of grasses according to their ability to produce leaves and the causes which influence leaf development; (5) the determination of seed mixtures adapted to certain conditions, and (6) investigation of meadow plants according to their nutrient material, the valuation and duration of meadows and of the meadow land itself.

Contributions from the U. S. National Herbarium, J. N. ROSE (*U. S. Dept. Agr., Division of Botany, Contributions from the U. S. National Herbarium, vol. I, No. 9, pp. 293–434, pls. 13, figs. 10*).—A report is given, containing critical notes and descriptions of new species, of a collection of plants made by E. Palmer in the States of Sonora and Colima, Mexico, during the years 1890 and 1891. The grasses were determined for this report by the late G. Vasey, the ferns by D. C. Eaton, the *Cyperaceæ* by N. L. Britton, the species of the genus *Piper* by C. de Candolle, the *Sapindaceæ* by L. Radlkofer, and assistance was given by others in various groups. An index of this completed volume is given in this number.

The influence of cold on plants—a résumé, C. ABBE.—In 1888 and 1891 Sebastiano Cavallero[1] published his original investigations confirming the results arrived at by German students a few years before as to the effect of frost upon plants. He states that until lately it was supposed that by the freezing of the sap the cells are distended and the tissues torn asunder, and that to this injury the death of the plant must be attributed. In the winter of 1887–'88 he ascertained that the frozen tissues did not suffer any injury, and repeated his observation in 1890–'91. He found that under the action of frost a rupture of the tissues is very rare and that the cells themselves never freeze; that the small crystals of ice are not formed within the cells, but in the intercellular spaces; and that this formation occurs both in the hardy and the delicate plants. It is the chemical changes brought about by frost that are of principal importance. So far as it goes Cavallero's work confirms that of Müller-Thurgau, published first in 1880, and subsequently elaborated and published in 1886. As his conclusions are not yet found in the text-books, it may be stated that in general as the temperature of the plant cools the water exuding from the individual cells leaves a more condensed sap behind and the intercellular spaces are filled with purer water. Owing to capillary phenomena this water is not easily frozen until it has been cooled several degrees below the freezing point, and then its temperature suddenly rises to 32° F., as in the ordinary experimentation of the physical laboratory. The water within the cells is of course not yet frozen, being a more condensed sap, whose freezing point is usually lower than that of pure water. If now the temperature falls still lower, the ice cools, and eventually the sap within the cells may be frozen, but this is rare, and when it happens it does not necessarily tear the cell wall, because the quantity within the cell is not more than sufficient to fill up the space formerly occupied by the water that exuded. If now the plant thaws out, the great mass of intercellular water escapes by transpiration. A little may go back into the cells, but this is a small percentage and oftentimes none. The plant wilts by the rapid loss of this water. Furthermore, a chemical change takes place in the cells by the excretion of pure water, and the cell sap that is left behind constitutes a new chemical compound. Such cells now change their character and their relation to the growth of the plant. Many of the excrescences and the diseases formerly supposed to be due to bacteria, or fungi, or parasites are found to be due to the chemical changes that have taken place within the cells in consequence of freezing. Thus Hartig shows that the frost *krebs*, or excrescence on trees, is a growth due to the effort of the plant to get rid of or cover up the dead cells produced by frost. When a frozen plant is young and tender and its leaves immature, the exudation through its tender cell walls may lie directly on the outside of the cuticle, but as the cuticle hardens in the mature plant, and the development of stomata becomes more complete, the greater part of the exuded water and its resulting ice is in the intercellular spaces. When the frozen plant is thawed out and evaporation is rapid the loss of water either from the surface of the tender plant or through the stomata of the mature plant is much more rapid than under normal conditions and the plant wilts, but when there is no evaporation, the sap has time to return into the cells, and the wilting is not so severe. Therefore it is proper to say that the injury is not done by the more or less rapid thawing, but by the more or less rapid evaporation that accompanies the thawing. If similar plants are thawed out under warm and cold water, respectively, the rate of thawing has no influence on its health, as was shown by Sachs long ago. It is now seen that this is because in both these cases there is no special chance for evaporation, and the sap was able to go back into the cells; the contrary occurs when the plant thaws in the open air.

---

[1] Gior. Agr., 1888, Mar. 11; Gaz. Mantova, 1891, Jan. 24.

It is commonly said that those plants and parts of plants which catch the early morning sun and are thawed out rapidly suffer in consequence, but it is now evident that two other factors have a predominating influence, viz, (1) the special evaporation in air and sunshine;

(2) the fact that these parts have, during the previous growth, been daily receiving extra sunshine and have thereby become more turgescent than the shaded portions. This has prepared their cells to suffer more from frost. Kunisch likens the chemical change that the sap undergoes in each cell to the freezing out of cryolites at specific temperatures from ordinary solutions; it is the chemical change that is the real cause of the death of the cells, and if too many cells are killed the whole plant succumbs. Moll shows that the wilting of the frozen leaves is due to the collapse of the cells whose exuded water has frozen in the intercellular spaces.

Sorauer traces the frost *brand* or blight, the frost *krebs* or cancer, the frost *beulen* or boils, the frost *leppen* or patches, and the frost *runzeln* or wrinkles and puckers to a healthy effort of the plant to get rid of or cover up the cells that have been killed by the frost. When a plant is abundantly supplied with warmth and moisture it suffers most from spring frosts; but when it has been retarded in its development, and especially when it is still in its winter stage of vegetative repose, it suffers least. When the autumn and early winter are warm and dry and the tree continues its growth late in the season the subsequent winter freezes are more injurious to it because in general there is more sap in its cells and more cells suffer from the chemical changes produced by the cold. R. Goethe collects a number of facts illustrating this general principle. He recommends that all frost wounds be cut out as soon as perceived and closed up with grafting wax; covering the wounds with clay may sometimes do, but in general fungi develop beneath that. The hot wax or wash with fungicides may kill the wood to the depth of a millimeter, but it preserves the rest. Goethe recommends to strip off the leaves in autumn, to loosen the earth about the roots, to whitewash the branches and trunks with lime and envelop them with straw. Sorauer has especially investigated both the mechanical and chemical injuries and the effects of temporary frosts and of long-continued freezes. Müller-Thurgau in 1886 summed up the experience of others and the thousands of experiments made by himself about as follows: The exudation of the sap from the cells and its freezing outside is the death process. Then the injury is done, the cell is dead from that time forth, but perhaps not the whole plant; no process of thawing will revive the dead cell or dead plant. As a protection against loss by frost he suggests: The proper selection of varieties which, in consequence of their origin, can be considered as able to resist frost; the new development of hardy varieties from such hardy individuals as may be occasionally discovered; the diminution of danger against frost by proper cultivation and nourishment and whatever makes the plant sound and vigorous, as suggested by the various experiences of severe winters; the acceleration of the beginning of the period of vegetative rest (stripping the leaves is considered to be without advantage) and the retardation of development—that is to say, the prolongation of this repose by protecting the plants and the soil from premature warmth. As external protections, he recommends covering the ground around the plants with earth or snow or mulching. He gives special attention to the smudging of the vineyards, with some historical details. We must refer to the original[1] for the many details which he gives as to the treatment of plants that have been injured by frost.

Since 1886 the following additions to our knowledge have been published. In 1886 Wollny[2] summarized our knowledge of methods of cultivation by which to assist cultivated plants in overcoming unfavorable climatic influences, especially frost. He lays principal stress upon the introduction of hardy varieties and shows that these may be developed by selecting the larger seeds. In general the plant has a greater resistance to frost in proportion as the seed from which it was developed is larger. Again, plants from unripe seeds possess a less resisting power to the frost than those from the developed seed. Again, a seed that develops prematurely in the fall has the greatest danger of suffering during the following winter. Finally, the plants stand the frost better in proportion as the seed is buried less deeply, since the seeds that are sown shallow give rise to the most vigorous plants.

Detmer[3] finds that perfectly dry grains and fruits exposed to —10° C. or lower retain their vitality, but that moist fruits and seeds are killed. Ordinary wheat kept at —10° C. loses much of its energy and speed of growth and is enfeebled apparently in proportion to its moistness. He agrees with Sachs that many plants die under rapid thawing that live under slow thawing, but that certain parts of plants die in consequence of freezing alone independently of thawing.

Kny[4] from his experiments as to whether frost acting on the seeds affected the subsequent development of the plant found that seeds of peas, beans, clover, rape, tobacco, and barley, when they were well dried and then divided into 3 groups, (1) those that were frosted, (2) kept cool, and (3) quite warm, and then planted, germinated and developed without any great difference; but seeds that were not well dried were injured by the cold.

Wollny[5] finds that potatoes are less in number and weight when the seed tubers have been long exposed to freezing.

L. H. Bailey,[6] has shown the good influence of wind-breaks in agriculture, including their advantages as a protection against freezing.

Jumelle[7] shows that although plants cease respiring at very low temperatures, yet in the presence of light they can assimilate the carbonic acid gas of the atmosphere at a temperature of −40° C., and that the so-called sleep, or vegetative repose, is due to the drying up of the plant and not to the cold.

Bliznine[1] shows that the freezing of wheat in a cold but snowless December does much more injury than in February, apparently owing to the early tender stage of growth.

Hartig[2] shows that the temperature under the bark of a tree after the leaves have fallen, and therefore in winter time, may be 50 or 55° C. on the sunny side, while the temperature on the shady side is 15 or 20° less. With this high temperature there comes a stimulated evaporation on the sunny side that separates the bark and kills the tree.

Petit[3] calls attention to the fact that as water in capillary vessels does not freeze until it is cooled down to a temperature far below that of melting ice, so in like manner the water in the soil which is spread in capillary films over each grain of gravel may be cooled to about 15° F. without freezing, but when it does change to ice it suddenly warms up to 32°. For this reason the temperature of the soil cools more rapidly during the nighttime in proportion as the soil is drier. On the contrary, in the summer time, when freezing does not come into play, the soil is warmer in proportion as it is drier.

Prunet[4] finds that on thawing the frozen plant the water is lost by evaporation from the surface rather than by the ordinary operation of transpiration through the stomata or breathing pores.

Schindler[5] in his extensive special studies on the relation of wheat to climate accepts the fact that wheat is less sensitive to frost in proportion as its vegetative period is longer, but thinks that no explanation is as yet known. The dry wheat of the Steppes does better than the moist wheat of western Europe. The power of resisting frost depends ultimately on the specific peculiarities of the protoplasm, about which we know nothing.

The effect of bad seasons on the growth of trees, A. CARY (*Garden and Forest, 8 (1895), pp. 88, 89*).—During the winter of 1893–'94 the author made a study of the so-called year rings of spruce trees, in the course of which the rings of over 1,400 trees in Maine were counted. In all trees of apparently more than 80 years' growth a belt was noticed in which the rings were greatly reduced in size, in some cases being seen only with the aid of a microscope. By reference to meteorological data of undoubted authority it was learned that a series of remarkably cold seasons began in 1812 and culminated in 1816, the years 1812, 1815, and 1816 being the most severe. The record of the effect of these years in the trees is usually represented by a zone of 6 or 7 greatly reduced rings. If each ring represents a year's growth the zone should begin with the seventy-seventh from the bark. In some cases this was found to be true, but more frequently there was a discrepancy of 3 or 4 rings. Counting from the inside of the zone of reduced rings to the bark a similar discrepancy is noted, showing that the number of rings can not be taken as a perfect index of the age of a tree, but shows the number of growth periods, which may be influenced by cold or drought, in which case several rings may be deposited during a single year, or in ordinary seasons an occasional extra ring may be deposited.

The paths of gaseous exchange between the aërial leaves and the atmosphere, F. F. BLACKMAN (*Proc. Roy. Soc., 57 (1895), No. 342, pp. 165–168*).—On account of the smallness of the quantities of gas involved, the author states that practically no attempt has been made hitherto to determine by direct estimation the question of the path by which carbonic acid passes out of the leaf in respiration and into it in assimilation—whether this takes place by the stomatal openings or through the continuous surface of the cuticle. The existing experimental evidence is all of an indirect nature, and rather tends to support the view that the exchange is a cuticular phenomenon. Barthélemy in 1868 put forth the view that the cuticle was especially adapted for transmitting carbon dioxid from the external air to the assimilating cells beneath. This view he supported by experiments on the artificial osmosis of gasses through leaves. About the same time Boussingault performed experiments that seemed to show definitely that in assimilation the carbon dioxid taken up by the leaf entered it through the upper surface devoid of stomata rather than through the more distant stomatal openings. In support of the view that stomata form the paths of gaseous exchange we have the conclusion arrived at by Mangin in 1888, from diffusion experiments on isolated cuticle, that this diffusion is insufficient to account for the whole gaseous exchange of the leaf. By the aid of an apparatus designed by the author he has been able to estimate successfully the amount of carbon dioxid given out and taken in by the two surfaces of the same leaf under the same conditions. For this purpose shallow capsules 10 sq. cm. in area, consisting of a glass plate with metal rim, through which tubes for the circulation of the air current pass, are employed. Two of them are affixed to a leaf on opposite sides of the same area in air-tight union by means of soft wax. Through these two continuous currents of air can be kept flowing over the two surfaces and the carbon dioxid produced or taken in during a given time by each of them be determined. Numerous experiments on the respiration of a variety of leaves with the stomata all on one side or variously distributed on the two sides agree in showing that the stomata are the site of the exhalation of this gas. When no stomata are present on the upper surface of the leaf then practically no carbon dioxid is exhaled from that surface, while more than thirty times as much may be given off from the lower stomatiferous surface. When stomata occur on both surfaces the relative amounts of the gas exhaled closely follow the ratios of the number of stomata. To prove this the author shows that *Ampelopsis hederacea*, with no stomata on the upper surface, but with many on the lower, exhales carbon dioxid in the proportion of 3:100 for the two sides; in *Alisma plantago* the proportion of the stomata on the two surfaces is as 135:100, and the proportion of the gas exhaled is as 120:100; in *Iris germanica*, with an equal number of stomata on each surface, the proportion of the gas exhaled by the two surfaces is as 110:100; and in *Ricinus communis* the proportion of stomata is as 100:250, and the gas exhaled is as 100:260.

Experiments in the absorption of carbon dioxid during assimilation showed the same close relation to the distribution of stomata. As hitherto carried out, the author considers direct sunshine, continuous for several hours, as essential to the success of these experiments. A very simple experiment of the author's will show that the stomata are practically the sole path of entry of carbon dioxid for assimilation. If part of the lower stomatic surface of any leaf, having no stomata on its upper surface, be coated with wax so as to mechanically block the stomata, no starch can be formed in that area, while adjacent areas may become rich in starch.

The previously mentioned experiments by Boussingault were conducted with the leaves of *Nerium oleander*, the upper surface of whose leaves possesses no stomata. These leaves assimilated less when the upper surface had been coated with wax than when the lower stomatiferous surface had been so coated. The author claims that the explanation of this is due to the fact that Boussingault experimented with the leaves in an atmosphere containing 30 per cent of carbon dioxid, which is greatly in excess of the optimum percentage of carbon dioxid assimilated by this leaf. Under these conditions there penetrates into the leaf so much of the gas that its assimilatory activity is lessened and falls below that of another leaf, into which, owing to the blocking of the stomata, the gas diffuses very slowly and can not exceed the optimum strength.

Further evidence on the possible paths of gaseous exchange has been obtained by investigating the degree to which diffusion of carbon dioxid can be artificially produced through the living leaf. Strong mixtures of the gas were led continuously across one surface of the leaf and the amount which diffused through it was estimated. Other experiments on the respiration of injected leaves also support the view that the stomatal openings, in spite of their minuteness, offer a much easier path from the atmosphere to the interior of the leaf than does the cuticle. The conclusions of the author are as follows:

"(1) Under normal conditions practically the sole pathway for carbon dioxid into or out of the leaf is by the stomata. Since oxygen diffuses more readily than carbon dioxid through fine openings, the same probably holds for oxygen and the whole of the gas exchange.

"(2) Under abnormal conditions, when the stomata or intercellular spaces are blocked and the surrounding tension of carbon dioxid is great enough, passage of carbon dioxid by osmosis through the cuticle may take place.

"(3) That such closure of stomata as is held to take place in darkness does not prevent the distribution of gas exchange closely agreeing with that of the stomata.

"(4) That the exhalation of carbon dioxid in bright light by a leafy shoot in Garreau's well-known experiment is not the expression of any physiological truth for the leaf, but only due to the imperfections of the conditions; to the presence of immature parts, or of tissues not sufficiently green or not fully illuminated. Mature isolated green leaves fully illuminated assimilate the whole of their respiratory carbon dioxid and allow none to escape from them."

The bacteria of the root tubercles of Leguminosæ, M. GONNERMANN (*Landw. Jahrb., 23 (1894), No. 4 and 5, pp. 649–671*).—The author has sought by means of pure cultures, soil investigations, and inoculation experiments to ascertain the probable number of forms of bacteria capable of forming tubercles on the roots of leguminous plants. The methods employed by the author are described very minutely. Plate, gelatin, and potato cultures were made of all forms found in the tubercles of *Lupinus albus*, *L. angustifolius*, and *L. luteus*, and the winter soil was carefully examined to learn how the organism passes the winter. He found in his cultures several forms of *Bacillus* and *Micrococcus*, and claims that those bacteria forming tubercles on the roots of legumes are spore forming, and in this way pass the winter in the soil.

From his experiments the author thinks that there is not so great a necessity for the presence of bacteria for nitrogen assimilation as is sometimes claimed, and that the relationship between the plant and the organism is often one of parasitism rather than of symbiosis.

The author concludes that (1) the tubercles of *Leguminosæ* are not formed by a single specific bacterium, but that in different localities are to be found different organisms capable of producing them; (2) the Y-formed specimens, the so-called bacteroids, are very complex while in symbiosis with the plant, but later upon the dissolution of the tubercles they separate into simple bacilli, and as such they may be found in the surrounding soil. In the spring they enter the plants and form by their growth into new Y-shaped bodies; (3) the symbiotic relationship is not yet completely established, since the tubercle bacteria alone can not make the free nitrogen available for the plant, but it seems more probable that the plant itself without symbiosis can take up and assimilate free nitrogen; the bacteria, however, may assist the plant in contributing to its higher nitrogen content. Further, it is shown that in spite of the presence of bacteria the plants do not take up any greater nitrogen content. From many recent experiments it is shown that not only a symbiotic but also a parasitic relationship exists between the plants and their bacteria, also that the effect of the bacteria and the method of nitrogen assimilation are not well known.

On the presence of alumina in plants and its distribution, BERTHELOT and G. ANDRÉ (*Compt. Rend., 120 (1895), No. 6, pp. 288–290*).—As a contribution to the question of the existence and proportion of alumina in plants the following determinations, among other data, are reported: Carefully washed alfalfa roots, 0.127 to 0.5 per cent of pure alumina; convolvulus roots, 0.0596 to 0.4 per cent; Bermuda grass roots, 0.011 to 0.12 per cent; lupine leaves, 0.013 to 0.037 per cent; linden leaves, 0.0012 to 0.0025 per cent.

These results indicate that alumina is present in considerable amounts in plants with extensive root systems, but that it remains largely in the roots and is found in only minute quantities in the leaves.

Report of the botanist, B. D. HALSTED (*New Jersey Stas. Rpt. 1893, pp. 289–436, figs. 73*).

Synopsis.—The author gives a report on weeds, potatoes grown directly from the cuttings, the solandi process of sun printing, and various fungus diseases (see p. 823).

Report on weeds (pp. 290–312).—The author prepared as a part of the Agricultural College and Experiment Station exhibit at the Columbian Exposition a collection of the most common weeds of the country, which were displayed in wing frames and as an herbarium. A case of 100 weed seeds was also shown. In collecting the material for this exhibit an opportunity was offered for extending the check list of American weeds, a revised list of which is given. This list embraces 817 species, representing 77 orders. An illustrated lecture upon weeds was prepared, a synopsis of which is given.

Potatoes by the direct method (pp. 312–318).—The author's attention was called to specimens of seed potatoes that failed to produce plants. In their stead small tubers were grown from the eyes, and all further development stopped. In a few cases there was a feeble attempt to send up shoots, but in all cases the yield was greatly reduced. Foreign truckers are said to sometimes take advantage of this habit to produce an early crop of potatoes. The reason for this unusual behavior seems to be physiological, and whatever tends to weaken the seed may under adverse atmospheric conditions produce the result given above.

The solandi process of sun printing (pp. 318–323).—This process consists in exposing the subject, necessarily somewhat translucent, to the sunlight in an ordinary printing frame with a sheet of sensitized paper back of it, as in the ordinary way of printing from a negative. This sun print when toned becomes the negative from which the pictures may be printed, a piece of glass being interposed between negative and print. The toning is done with kerosene for both negative and positive. As the object must be translucent, the uses to which this method can be placed are limited, but any object that will allow any light to penetrate may be so photographed if exposed long enough. Leaves, thin sections of wood, rusts, leaf spots, blights, etc., are especially adapted to this process. This method of printing is not new, but the use of kerosene as a clarifying agent is the chief point of interest, as it diminishes the time required for exposure and sharpens the details of the positive picture.

Shrinkage of leaves in drying (pp. 323–326).—Numerous leaves were printed by the solandi process, after which they were prepared for the herbarium in the usual way. A table is given showing that endogens shrink less than exogens, the average of 4 endogens being 18 per cent, with 11 per cent for *Pontederia* and 27 per cent for a *Panicum*, while the average of 7 exogens was 31 per cent in drying, the extremes being 21 per cent for hollyhock and 45 for a catalpa leaf. A study of the outlines shows that leaves shrink most in the region of fewest veins, and the author gives the following law: "Leaves in drying under pressure shrink toward the mass center of their framework."

Botanical work at the Mississippi Station (*Mississippi Sta. Rpt. 1893, p. 47*).—A brief mention of the nature of the botanical work being carried on at the station, which is chiefly devoted to a botanical survey of the State, comprising a collection and study of the flowering plants, and also of the mildews, rusts, smuts, and other parasitic fungi.

A model for a botanical course, G. Haberlandt (*Bot. Centbl., 61 (1895), No. 7, pp. 241, 242*).

On the list of Pteridophyta and Spermophyta of northeastern America as prepared by the nomenclature committee of the Botanical Club, B. L. Robinson (*Bot. Gaz., 20 (1895), No. 3, pp. 97-103*).—The author gives numerous instances in which the rules of the committee do not secure the much desired stability of nomenclature, and advances opinions why their rules will not secure the desired results.

The fundamental difference between plants and animals, C. S. Minot (*Science, n. ser., 1 (1895), No. 12, pp. 311, 312*).—The author holds that plants obtain their food, either liquid or gaseous, by osmosis; and animals in the form of concrete particles which are lodged in the cell protoplasm by the activity of the protoplasm itself. Apparent discrepancies are offered in the case of the Myxomycetes and the tape worm, the one usually classed with plants taking its food by an amœba-like method, the other living as a parasite by absorption.

The plant individual in the light of evolution, L. H. Bailey (*Science, n. ser., 1 (1895), No. 11, pp. 281-292*).—The author discusses bud variation in its relation to Weismannism. He considers the theory of Weismann inadequate to explain bud variation.

What constitutes metamorphosis in botany, A. Mann (*Inaug. Dissertation, Munich, 1894, pp. 40, figs. 25; abs. in Bot. Centbl., 61 (1895), No. 7, pp. 264, 265*).—The author discusses the morphology of sprouts, (*a*) tendrils, (*b*) thorns, and of leaves, (*a*) bud scales, (*b*) phyllodia, (*c*) tendrils, and (*d*) thorns.

The geotropic curving of nodes, R. Barth (*Inaug. Dissertation, Leipzig, 1894, pp. 39; abs. in Bot. Centbl., 61 (1895), No. 10, pp. 364, 365*).

Contraction of trees caused by cold, J. Clayton (*Nature, 51 (1895), p. 462*).—The author gives measurements of 13 trees measured October, 1894, and February and March, 1895, showing a contraction for February, when the temperature was 3° F., varying from $\frac{2}{16}$ to $\frac{6}{16}$ of an inch in circumference.

On the forms of chlorophyll, A. Etard (*Compt. Rend., 120 (1895), No. 6, pp. 328-331*).—The author has separated from afalfa a second form of chlorophyll, the formula of which is $C_{42}H_{63}NO_{14}$.

On the forms of chlorophyll, A. Gautier (*Compt. Rend., 120 (1895), No. 7, pp. 355, 356*).—Remarks on articles by Etard (*Compt. Rend., 119 (1894), p. 219, and 120 (1895), p. 328*). The author states that he (Gautier) showed in 1877 that there were different kinds of chlorophyll in different orders and genera of plants. He had separated the principal chlorophyll of rye grass and spinach in 1886, the formulas for which are given as $C_{30}H_{48}N_2O_3$ for the rye grass, and $C_{40}H_{64}N_2O_4$ for the spinach.

A preliminary investigation of the presence of diastase in plants, J. Gruss (*Ber. deut. bot. Ges., 13 (1895), No. 1, pp. 2-14*).

Root tubercle bacteria, Danckelmann (*Ztschr. Forst. und Jagdw., 27 (1895), No. 2, pp. 90, 91*).

Do plants assimilate argon? E. BLASS (*Nature, 51 (1895), p. 461*).—The note by Blass is answered by W. Ramsey, one of the discoverers of the new element, that experiments are under way by which the question can be answered.

Primitive corn (*Meehan's Monthly, 5 (1895), No. 3, p. 44, fig. 1*).—An account of sexual abnormalism in an ear of corn—the pistillate and staminate flowers mixed.

A new method for investigating the carbonic acid gas exchanges of plants, F. F. BLACKMAN (*Proc. Roy. Soc., 57 (1895), No. 342, pp. 162–164*).—An abstract is given briefly describing a form of apparatus designed to measure small quantities of carbonic acid gas given off by parts of leaves.

Apparatus for physiological botany, W. C. STEVENS (*Bot. Gaz., 20 (1895), No. 3, pp. 89–96, pls. 4*).—Descriptions are given of a centrifugal machine and three forms of clinostats—a horizontal, vertical, and universal clinostat.

Flowers and Insects, XIII, C. ROBERTSON (*Bot. Gaz., 20 (1895), No. 3, pp. 104–110*).—The author discusses the mutual relationship between the flowers of *Dodecatheon meadia, Steironema ciliata,* and *Enslenia albida,* and the insects found to visit them.

Phenological observations in Metz during the years 1891–'94. SCHÄFER (*Jahresber. Ver. Erdkunde in Metz, 16 (1893–'94)*).

ZOÖLOGY.

Monographic revision of the pocket gophers, family Geomyidæ, C. H. MERRIAM (*U. S. Dept. Agr., Division of Ornithology and Mammalogy, North American Fauna, No. 8, pp. 258, figs. 71, pls. 20, maps 4*).—An illustrated monograph of the pocket gophers, exclusive of the genus *Thomomys*, giving detailed technical, anatomical, and systematic descriptions of the various species, with notes on habits. It is divided into introduction, and 4 chapters: General remarks; morphology of the skull; the dental armature, comprising the teeth and the mechanism and dynamics of the cutting machine; and systematic descriptions of the genera and species. The genera *Pappogeomys*, *Cratogeomys*, *Platygeomys*, *Orthogeomys*, *Heterogeomys*, *Macrogeomys*, and *Zygogeomys*, and the following species and subspecies are described as new: *Geomys tuza mobilensis*, *G. breviceps sagittalis*, *G. breviceps attwateri*, *G. texensis*, *G. arenarius*, *G. personatus fallax*, *Pappogeomys albinasus*, *Cratogeomys perotensis*, *C. estor*, *C. peregrinus*, *C. oreocetes*, *C. castanops goldmani*, *C. fulvescens*, *Platygeomys tylorhinus*, *P. planiceps*, *Orthogeomys latifrons*, *O. nelsoni*, *Heterogeomys torridus*, *Macrogeomys dolichocephalus*, *M. costaricensis*, and *Zygogeomys trichopus*.

Pocket gophers and moles, C. L. NEWMAN (*Arkansas Sta. Rpt. 1894, pp. 108–113*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 389).

METEOROLOGY.

Frost warnings, J. M. SHIRIER (*Proc. Ga. Hort. Soc. 1892, pp. 56–58*).—Brief general note on Georgia weather service and the methods of sending out information as to the approach of frosts. It is recommended that smudges be used for protecting plants from early frosts. Piles of slowly inflammable material, such as green pine butts, are to be made and lighted, at least 4 smudge piles being employed for every 160 acres of ground. It is believed the smudge would be dense enough to envelop surrounding vegetation and protect it from frost, as is done successfully on the prairie lands of Minnesota.

Prediction of night frosts in the spring, C. ROUSSEAU (*Rev. Hort., 67 (1895), No. 3, pp. 71–74*).—The results of observations from March 20 to May 20 during the years 1880–'94 are reported, showing that the average difference between the reading of the wet-bulb thermometer during the afternoon and the minimum thermometer the following night was 4.8° C., thus in a measure confirming the accuracy of Hammermann's statement that frost may be expected if the reading of the wet-bulb thermometer in the afternoon minus 4° is 0 or less. A closer analysis of the results, however, shows that this factor is by no means constant, but depends largely upon direction of the wind, cloudiness, rainfall, etc.

The use of a somewhat larger factor than 4° is recommended as generally safer in practice. In fair weather, with the wind north or northeast, the difference is nearer 7 or 8 than 4°.

Meteorological observations at Berkeley, California, L. E. HUNT (*California Sta. Rpt. 1893 and 1894, p. 362*).—A synopsis of observations for 7 years ending June 30, 1894, on air pressure, temperature, precipitation, humidity, cloudiness, and direction of wind. The summary for the year ending June 30, 1894, is as follows: *Pressure* (inches).—Mean, 30.059; highest, 30.440 (Dec. 28); lowest, 29.682 (Feb. 12); yearly range, 0.758; highest monthly average, 30.183 (December); lowest monthly average, 29.921 (August). *Temperature* (°F.).—Mean of the year, 50.2; mean of the warmest month, 59 (July); mean of the coldest month, 44.2 (January); maximum, 79.5 (April 19); minimum, 31 (January 6); yearly range, 48.5; greatest monthly variation, 40 (April); least monthly variation, 25 (September); mean daily range, 14.4; mean lowest, 47.7; mean highest, 62.1. *Precipitation* (inches).—Total rainfall, 26.650; dew and fog, 0.084. *Humidity.*—Mean relative, 82.8; greatest monthly variation, 52 (November); least monthly variation, 26 (August); maximum, 97 (November 24, 8 a. m.); minimum, 45 (November 17, 8 a. m.); yearly range, 52. *Weather.*—Number of clear days, 163; number of fair days, 93; number of cloudy days, 109; number of foggy days, 107; number of days on which rain fell, 68. *Wind.*—Prevailing direction, southerly.

Report of meteorologist, W. H. BISHOP (*Delaware Sta. Rpt. 1893, pp. 203–217*).—Monthly summaries of observations at 6 stations in the State on temperature, pressure, and rainfall are given. A summary of temperature and rainfall observations for the year 1893 is given in the following table:

Annual summary of meteorological observations in Delaware.

	Newark.	Middletown.	Dover.	Milford.	Seaford.	Millsboro.
Temperature (°F):						
Highest	97.00	96.00	101.00	95.00	97.00	97.00
Lowest	− 9.00	− 5.00	− 6.00	− 9.00	− 5.50	− 17.00
Mean	50.90	51.30	52.50	53.80	53.60	53.50
Rainfall (inches), total	36.29	41.15	42.10	40.45	40.62	44.02
Number of days on which 0.01 inch or more of rain fell	87	91	92	94	89	101

The mean temperature was slightly lower than for the past 3 years. The hottest days were June 20 and July 26, the difference in temperature between the two being very slight. The coldest day was January 17. The rainfall for the year is slightly below the average, the greatest deficiency occurring in June. Damaging storms occurred August 23 and 24 and October 13 and 14. The first killing frost occurred October 17.

Meteorological summary (*Mississippi Sta. Rpt. 1893, p. 62*).—The results of observations during 5 years (1889–'93) on temperature and rainfall are tabulated. The following summary is taken from the tables reported:

Meteorological summary for Mississippi, 1889–'93.

	1889.	1890.	1891.	1892.	1893.
Temperature (°F.):					
Maximum	97.00	96.00	97.00	96.00	[1]99.00
Minimum	15.00	19.00	19.00	13.00	[2]9.00
Mean	62.90	64.90	63.60	62.50	62.90
Rainfall (inches)	44.96	55.05	61.17	59.78	40.17
Number of rainy days	78	94	84	101	86

[1] July. [2] January.

The average yearly rainfall for the 5 years was 52.23 in., the highest average monthly rainfall being 7.11 in. in July, the lowest 1.03 in. in October.

Protection from night frosts, S. LEMSTRÖM (*U. S. Patent No. 525989, Sept. 11, 1894*).—An account of the method of protection for which this patent is issued has already been noted (E. S. R., 5, p. 660).

Meteorology (*Arkansas Sta. Rpt. 1894, pp. 51, 52*).—A reprint from Bulletin 26 of the station (E. S. R., 5, p. 1070).

Meterological observations at Newport and Camden, Arkansas, G. B. IRBY and F. H. CLARKE (*Arkansas Sta. Rpt. 1894, pp. 86, 114*).—Daily summaries, April to October, 1893, of temperature and rainfall observations at Newport and summaries of similar observations for each month of 1893 at Camden.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 22 (1894), Nos. 7 and 8, pp. 273–350; charts 8*).—These numbers are devoted to the usual topics.

Periods in temperature, H. A. HAZEN (*Amer. Met. Jour., 11 (1895), No. 11, pp. 416–418, dgm. 1*).—Summations of temperature fluctuations over the whole United States during 27-day periods in the 9 colder months of the year are projected in a diagram. "There is absolutely no period established in these cases."

The occurrence of cold days (*Nature, 51 (1895), No. 1322, pp. 416, 417*).—The maxima for 50 winters at Greenwich are tabulated and discussed and maxima not over 32° F. are charted.

New relations between the movements of the barometer on the northern hemisphere and the movement in declination of the sun and moon, P. GARRIGON-LAGRANGE (*Compt. Rend., 120 (1895), No. 6, pp. 342, 343*).

Variations in the rainfall in European Russia, E. A. HEINZ (*Bul. Acad. Imp. Sci., St. Petersburg, ser. 5, vol. 2, No. 1, pp. 49–54, pls. 2*).

Harrington's rainfall charts—a review (*Science, n. ser., 1 (1895), No. 12, p. 319*).

A new form of barometer, J. N. COLLIE (*Jour. Chem. Soc. London, 1895, Feb., pp. 128–132, fig. 1*).

WATER—SOILS.

The cienegas of southern California,[1] E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 185–188*).—"A *cienega*, in the parlance of the native Californian, is a limited area showing a growth of water-loving plants, appearing sporadically in otherwise arid surroundings—usually hillsides or valley margins—and occasionally giving rise to flowing springs." The cienegas of the San Antonio, Santa Ana, and Mill creeks, and of the Temescal Valley, are described and their value as sources of water supply discussed.

"While they do not render the establishment of artificial storage reservoirs superfluous, they do supplement them locally to a very material extent, rendering it possible to occupy for agriculture large areas that otherwise would have remained arid for many years to come.

"But there arises the question as to the geographical limits within which these natural storage reservoirs may reasonably be sought, for it is notorious that they are not usually found, and the name and idea of the cienega is not generally known in the northern portions of California.

"The essential condition of cienega formation is manifestly the opportunity for the abundant formation of deposits of exceptionally coarse and pervious gravel and cobbles near the points where the canyons emerge from the mountains. This, again, is necessarily conditioned upon the occasional occurrence of violent, torrential rainfall in the mountains, alternating with periods when quiet deposition allows of the formation of water-shedding layers. Another condition appears to be the ready weathering of the parent rocks into rounded forms, by which close packing is prevented, so that abundant interspaces are permanently maintained. Both conditions are fulfilled to an unusual extent in the granitic ranges of southern California."

Investigations in soil physics, R. H. LOUGHRIDGE (*California Sta. Rpt. 1893 and 1894, pp. 70–100, dgms. 2*).—The results of examinations of a large number of different soils made at intervals during the past 15 years at the California Station are summarized in this article, "in order to draw as far as possible some conclusions, either positive or negative, as to the relation of the various sediments or ingredients to the power possessed by soils to absorb hygroscopic moisture, to their capacity for holding water, and to their power of transmitting water by capillarity." A somewhat detailed discussion is given of the influence of physical constitution and chemical composition of the soil on its hygroscopicity, especial attention being given to the influence exerted by clay; the methods and results of studies of the water-holding capacity of different soils, and the rapidity, height, and extent of the capillary rise of water in soils of different character subjected to different treatment.

The general conclusions drawn are as follows:

"(1) The power possessed by soils of absorbing moisture from the atmosphere and to hold water within their pores is not proportionate alone to the amount of combined surface presented by the particles of the soil; and while, as a very general class, soils with large percentages of clay and fine silts have a high moisture and water capacity coefficient, such materials by no means control that power, simply because of large surface area; for even in the small number of soils represented in the above analyses there are many which, though having very high clay percentages, are low in their moisture and water coefficient, and *vice versa*.

---

[1] Read at the meeting of the Geological Society of America at Washington, August, 1891.

"(2) There are in the soil certain chemical compounds (zeolites, ferric, silicic, and aluminic hydrates and humic compounds), which are highly hygroscopic and absorptive in themselves, and are held almost exclusively by the clay in greater or less amounts. The proportion of these, singly or conjointly, seems to have a greater, if not a controlling, influence over that power than the mere amount of clay and fine material, as such.

"(3) The upward movement of water in soils is controlled in rapidity by the proportion of coarse material; and the limit in height to which water will rise by capillarity is dependent upon the amount of fine silt and clay. The extreme height reached thus far, under the most favorable conditions, is 50 in., even after several months. In sandy soils the limit was less than 18 in.

"(4) The presence of alkaline salts in a soil produces a puddling or deflocculation of the particles when wet, and a consequent compact condition, which prevents the rapid rise of water. This puddling is accompanied by large contraction of volume, a feature which to a far less degree has been observed in other soils. On the other hand there are some soils (adobes and certain ferruginous clays), which, when wet, expand quite considerably, because of the swelling of the colloidal particles.

The amount and kind of soluble salts present in different portions of an alkali spot, from the center to the circumference, C. Colemore and E. W. Hilgard (*California Sta. Rpt. 1893 and 1894, pp. 140–145*).—Tabular statements of analyses showing the amount and composition of the alkali salts taken at 5 different distances from the center of an alkali spot are reported and discussed. It was observed that there was a more or less regular decrease in the amount of the alkali salts toward the margin, beyond which normal vegetation would thrive. In this case the maximum amount "found to be compatible with ordinary (weed) vegetation was 0.23 per cent, or a little less than a quarter of 1 per cent of total soluble salts, of which, however, one third was carbonate of soda and nearly another third common salt, or nearly 0.08 per cent of the soil of each." It has been observed, however, that this amount of carbonate of soda in an adobe soil is sufficient to prevent the growth of any useful plant. "It is therefore obvious that the mere determination of the amount of total salts present in a soil is not sufficient to determine its fitness or unfitness for crop growth. It is essential that the nature and proportion of the different salts present should be determined before a definite judgment can be had."

The analyses show further that the alkali containing the highest amount of carbonate of soda also contained the largest proportion of organic matter; that the per cent of soda steadily increased from the margin toward the center, while the reverse was true for potash; that carbonic acid and phosphate increased from the circumference toward the center; that chlorin decreased from the margin toward the center, while the proportion of nitrates was greatest at a point about halfway between the margin and center.

Reclamation of alkali land with gypsum at the Tulare Station, C. H. Shinn and E. W. Hilgard (*California Sta. Rpt. 1893 and 1894,* *pp. 145–149, pls. 3*).—This is an account of a continuation of experiments described in the Report of the Station for 1891–'92, pp. 80–'90 (E. S. R., 5, p. 569), the treatment tried in the earlier experiments on a small scale (¼-acre plat) on underdrained soil being extended to a larger area (¾ acre), which had not been underdrained, but had had the hardpan broken up by blasting.

"The total amount of gypsum used upon the acre now under treatment is 3,000 lbs. Only 625 lbs. has gone on the first one fourth acre, which was underdrained. This was at the rate of 1¼ tons to the acre. The plats on which blasting powder was used have required 2,375 lbs. of gypsum, or at the rate of nearly 3,200 lbs. to the acre, and are not yet as far reclaimed as the first plat. They will probably require half a ton more to yield wheat and barley at the rate of last year's crop on the smaller plat. The gypsum is evidently distributed more evenly and therefore more effectively by the method of underdraining, where the conditions are similar to those that prevail at the Tulare Station. . . .

"The cultures attempted in the spring of 1892 were more varied than before, embracing beets, corn, sorghum, cereals, grasses, clovers, and some garden crops. Most of these were sown in short rows near the middle of the plat, and the rows received a special application of gypsum to better protect the seed. Results showed the effect of the underdrains; the nearer the plants stood to the line of a drain the better they grew. While many cultures failed entirely, there was much to encourage hopefulness. Sorghum and Egyptian corn in some cases grew 6 or 7 ft. high, and yielded heavily. Close beside such plants as these were others hardly 3 in. high, pigmies of the same age, stunted by the alkali. A few barley plants were normal, but most of them when headed out were only 3 or 4 in. high. It was evident that the leaching of the plat had been very uneven, owing to the hardness of the soil; and most of the gypsum used in 1892 was used upon the spots where the alkali still remained strongest. . . .

"On the three fourths of an acre where blasting powder had been used . . . the leaching proceeded more slowly than on the first plat, but good progress has been made, and another season a fair crop of wheat and barley can be expected."

A new simple method of determining lime in arable soils, A. DE SAPORTA (*Compt. Rend., 120 (1895), No. 4, pp. 215–217*).—A known weight of the soil to be examined is dropped into a measured quantity, say 200 cc., of hydrochloric acid of known specific gravity (1.1 at 15° C.), and after solution is complete the increase in specific gravity of the acid is determined. It is claimed that in experiments with pure marble the increase in specific gravity was directly proportional to the amount of marble used, and so in examining soils the readings of the hydrometer may be taken as indicating the amount of lime dissolved. Results obtained by this method and by Bernard's calcimeter on 4 samples of soil show close agreement. The merit of extreme simplicity claimed by the author for his method appears to be about the only one it possesses.

Comparison of the action of hydrochloric and oxalic acids in soil extraction, M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 63–65*).—Two soils, a black adobe and a reddish sandy soil, were each digested in porcelain beakers for 5 days in the usual way in hydrochloric acid of 1.115 sp. gr. and oxalic acid of a corresponding strength.

The hydrochloric acid extract was analyzed in the usual manner.

"In the case of oxalic treatment, the solution was immediately filtered from the insoluble residue; the filtrate evaporated to dryness in a platinum basin, ignited to expel the excess of oxalic acid, and the resulting residue dissolved in hydrochloric acid and treated as usual."

"[The results] show that, on the whole, hydrochloric acid exerts a stronger influence on the soil than does oxalic acid, as in both sets of analyses it is noticed that the insoluble residue is, in the case of the hydrochloric acid digestion, about 2 per cent lower than is that resulting from the action of oxalic acid.

"The amount of potash (0.73 for the adobe and 0.47 for the sandy soil) dissolved is identical in the two treatments, while the quantity of lime extracted by hydrochloric acid is about twice that yielded by the oxalic acid, as is indicated by the figures 1.15 and 0.62 for the adobe soil, and 0.97 and 0.41 for the sandy. As regards magnesia, there is very little difference.

"The percentages of iron and alumina are both lower when oxalic acid is used as the solvent. . . .

"In summing up we might say that, except in the case of lime, the results obtained by the action of oxalic acid on soils could receive the same interpretation as that given to those derived from the hydrochloric acid treatment."

Digestion of soils for analysis, E. W. HILGARD and M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 61–63*).—In order to ascertain whether the acid commonly used in soil analysis undergoes change of strength in digestion on the steam bath, "50 cc. of hydrochloric acid, of 1.116 sp. gr., obtained by the distillation of the last two thirds of stronger acid under atmospheric pressure, was evaporated on the steam bath to one half its bulk. The same, diluted with 10 per cent of water, was similarly treated. Furthermore, the same experiment was made with 2 porcelain beakers ('soil pots') covered with watch glasses, being kept on the steam bath for 5 days, as usually practiced by us in soil digestion. In the latter two cases, the bulk had been reduced to 36 cc., or by somewhat over one fourth of the original volume."

The results were as follows:

Effect of evaporation on the strength of hydrochloric acid of 1.116 specific gravity.

	Strength of acid (anhydrous hydrochloric acid).		
	Original.	Evaporated to one half its bulk.	Evaporated to 5 cc.
	Per cent.	*Per cent.*	*Per cent.*
Desk acid in open beaker	22.96	21.49	20.96
Desk acid with 10 per cent water	20.67	21.49	....
Desk acid in covered porcelain beaker	22.96	21.49	....
Desk acid, with 10 per cent water, in covered porcelain beaker	20.67	21.49	....

"It will thus be seen that under the ordinary conditions of digestion, as heretofore practiced in this laboratory, the changes arising from evaporation are absolutely insignificant, in comparison with those unavoidably resulting from the variable amount of soluble matters in different soils."

Analyses of water and remarks on water supply, M. E. JAFFA, M. CURTIS, and E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 157–184*).—**Analyses of a large number of samples of stream, lake, spring, well, and artesian water are tabulated and discussed.**

The influence of geological-agronomical charting upon soil study, T. WOELFER (*Fühling's landw. Ztg., 44 (1895), No. 2, pp. 42–49*).

Crops and fertilizers, with reference to California soils and practice, E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 200–213*).—A popular article discussing the draft of different crops on the soil and means of restoring exhausted fertility.

The relations of soils to climate, E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 100–139*).—A partial and revised reprint of Bulletin 3 of the Weather Bureau of this Department (E. S. R., 4, p. 276).

Fig soils, M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 235–240*).—A reprint of an article published in Bulletin 102 of the station (E. S. R., 5, p. 286).

On the nitrogen contents of soil humus in the arid and humid regions, E. W. HILGARD and M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 66–70*).—A reprint of an article in Agl. Sci., 8 (1894), No. 4, pp. 165–171 (E. S. R., 6, p. 197).

Analyses of alkali (*California Sta. Rpt. 1893 and 1894, pp. 149–156*).—Reports of examinations of 22 samples of alkali leachings, crusts, and soils.

Analysis of two Kentucky blue-grass soils, M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 65, 66*).—The results of analysis of 2 samples of Kentucky soils sent out by the reporter on soils and ash of the Association of Official Agricultural Chemists are tabulated and discussed. Attention is especially called to the high percentages of phosphoric acid, 0.71 and 0.40 per cent. The only soils having amounts approaching these figures are the black waxy soils of Texas, with 0.59 per cent, and basaltic soils of Montana, with 0.59 per cent.

Analyses of rocks, clays, marls, etc. (*California Sta. Rpt. 1893 and 1894, pp. 189–191*).—Brief reports of analyses of marl and clay rock, calcareous rock, cement, peat, borate of lime, and brine; and a list of minerals sent to the station for examination.

Analyses of soils (*California Sta. Rpt. 1893 and 1894, pp. 47–61*).—Mechanical analyses and in most cases chemical analyses of 3 samples of soil from the Sierra Foothills, 7 from the Great Valley, and 4 from the Coast Range are tabulated and discussed, and lists of a large number of samples subjected to partial examination are given.

Analyses of Malmesbury soils, C. F. JURITZ (*Agl. Jour. Cape Colony, 8 (1895), No. 4, pp. 76, 77*).—A continuation of systematic determinations of water, organic and volatile matter, chlorin, lime, potash, and phosphoric acid in the soils of Cape Colony. For previous analyses of soils of the Durban and Koeberg districts see same journal, Jan. 11, 1894, p. 5. Determinations of nitrogen are in progress and soil maps and charts are in course of preparation.

Progress in the culture of sandy soils in the last 15 years, B. MARTINY and A. ORTH (*Jahrb. deut. landw. Ges., 9 (1894), pp. 511–539*).

Reclaiming coast sands, C. B. MCNAUGHTON (*Agl. Jour. Cape Colony, 8 (1895), No. 2, pp. 57–65, figs. 14; No. 3, pp. 57–59, figs. 6; No. 4, pp. 91–96, figs. 6*).—An account of the methods used on the sand dunes of Gascony, France.

FERTILIZERS.

Green manuring with cowpeas and other crops (*New Jersey Stas. Rpt. 1893, pp. 146–150*).—This article gives the plan of an experiment for the improvement of light lands by the use of crimson clover and cowpeas, and a statement regarding the method of cultivating cowpeas on a large scale in New Jersey. Cowpeas, following crimson clover, yielded at the rate of 14,400 lbs. of green material per acre. The vines contained 2,278.1 lbs. of organic dry matter, 70.6 lbs. of nitrogen, 17.3 lbs. of phosphoric acid, and 50.4 lbs. of potash. The roots on 1 acre weighed only 1,080 lbs. and contained 295.2 lbs. of organic dry matter, 4.2 lbs. of nitrogen, 1.5 lbs. of phosphoric acid, and 4.4 lbs. of potash per acre. The roots and vines grown on an acre contained a total of 34.8 lbs. of nitrogen, 18.8 lbs. of phosphoric acid, and 54.8 lbs. of potash. The nitrogen in the vines is equivalent to that contained in 437½ lbs. of nitrate of soda, and is valued at about $11.

Report of pot experiments with phosphates, W. H. BISHOP (*Delaware Sta. Rpt. 1893, pp. 193–202, figs. 2*).

Synopsis.—In comparative tests of soft Florida phosphate, crude iron and alumina phosphate, concentrated iron and alumina phosphate, and acid phosphate, combined with nitrate of soda and muriate of potash on soja beans grown in 3 series of pots containing (1) 16 lbs. of clayey soil, (2) 20 lbs. of sandy soil, and (3) 20 lbs. of ground quartz, the first two phosphates gave no increase in crop; the last two increased the yields equally.

The soft Florida phosphate used contained 28.81 per cent of insoluble phosphoric acid, the "raw ground rock" (iron and alumina phosphate) 36 to 38 per cent of insoluble phosphoric acid, the concentrated phosphate (of iron and alumina) 38 to 40 per cent of available phosphoric acid and 49 to 50 per cent of total phosphoric acid, and the acid phosphate 15 per cent of phosphoric acid. These were each applied, at rates furnishing the same amounts of phosphoric acid, in combination with muriate of potash and nitrate of soda, in 3 series of galvanized iron pots containing different kinds of soil, viz, a clayey soil from the station grounds (16 lbs. per pot), a sandy soil from near Dover, Delaware (20 lbs. per pot), and ground quartz (20 lbs. per pot). In case of the sandy and clayey soils an additional pound of sand was added to the surface of each pot. For comparison some of the pots received gypsum alone and combined with muriate of potash and nitrate of soda, and others received no fertilizer. The soils were carefully mixed and sifted and the fertilizers thoroughly incorporated with them. Soja bean was the plant used. The pots were watered when it seemed necessary, the amount of water applied at each watering being 70 per cent of that which the soil would hold at saturation. The tabulated data show for each series the kind and amounts of different fertilizers applied, the water added, and the yields of stems (without leaves) and beans on each duplicate plat and the average yields.

The conclusions reached were as follows:

"(1) Soft Florida phosphate and 'raw ground rock' (iron and alumina phosphate) gave no increase in the crop.

"(2) 'Concentrated phosphate' gave as good results as acid phosphate.

"(3) When a full supply of water is added to soil that is already in a fair state of fertility the differences in the crop produced by the addition of fertilizers, even in large quantities, are not very great."

Methods of preparing phosphates of alkalies from phosphates of lime and iron, E. A. SCHEIDER (*Chem. Ztg., 19 (1895), No. 10, Repert., p. 34; Ztschr. angew. Chem., 1895, No. 4, p. 109*).—The following method is applicable to natural phosphates of lime, Thomas slag, and phosphates rich in iron oxid. The phosphate is dissolved in sulphuric acid, which is used in large excess when the iron content is low. In this case the excess of sulphuric acid is saturated with iron hydrate which is obtained as a by-product in a subsequent stage of the process. To the solution of phosphate of iron in sulphate of iron thus obtained water is added, which precipitates a considerable portion of the phosphate of iron. The solution remaining is used for the decomposition of another portion of phosphate, additional sulphuric acid being added to it. The phosphate of iron obtained is decomposed with potash solution, or if an apparatus for dialysis on a large scale is provided an ammoniacal solution of the phosphate of iron may be dialyzed to the point where the phosphate of ammonia disappears and the undecomposed residue of phosphate of iron is then treated with potash solution.

The solubility of basic slag, C. H. RISDALE (*Chem. News*, *71* (*1895*), *No. 1838*, *pp. 82*, *83*).—In this paper, read before the Cleveland Institute of Engineers January 14, 1895, the author criticises Wagner's conclusions regarding the relation between citrate solubility, silica content, and fertilizing value of slags (E. S. R., 6, p. 625). He especially dissents from the expression of results in terms of percentage solubility.

Investigation showed that tetrabasic phosphate of lime, whether natural or artificial, was completely dissolved in Wagner's citrate solution, and "that increased quantities of poorer slags, containing the same quantity of soluble phosphoric acid as richer varieties, and which should, when treated with fixed quantities of solvent (as would under actual agricultural conditions be the case), yield an equal amount [of phosphoric acid], do not, but yield much less." It was also shown that "the alleged close relation between the silica content and the percentage solubility had almost as many exceptions to the rule as examples of it, and that there was a point beyond which the higher the silica the less the solubility."

A study of the conditions influencing solubility lead to the following conclusions:

"The percentage solubility depends on—

"(1) The actual content of phosphoric acid, varying inversely to it.

"(2) The neutrality or freedom from excess of lime (and possibly certain other bases).

"(3) Silica does not *per se* increase this, but only (*a*) when it combines with and thus neutralizes excess of lime, and possibly certain other bases; (*b*) when as a condition of the presence of a large quantity of silicate of lime (which silicate appears not to interfere with the solubility in the quantities in which it is generally present) there is only a low total percentage of phosphoric acid present.

"(4) Silica decreases this when present in quantities greater than required in 3, or sufficiently large to bring about the formation of silicates of iron or manganese.

"(5) Excess of oxids of iron and manganese have a very small effect, almost negligible when compared with that of lime, the actual solubility being the resultant of the inert action of such of these conditions as are present.

"The absolute solubility, or actual amount dissolved, depends on the actual content of phosphoric acid, varying directly with it, and in other respects following 2, 3, 4, and 5."

Fertilizer inspection and analyses in New Jersey (*New Jersey Stas. Rpt. 1893, pp. 17–103*).—This includes statistics of the fertilizer trade in 1893 and 10 preceding years; data as to the market prices of fertilizers; remarks on the economic purchase and rational use of complete and incomplete fertilizers, and on formulas, composition, and cost of home mixtures; and tabulated analyses of 405 samples of fertilizing materials, including nitrate of soda, sulphate of ammonia, dried blood, dry ground fish, cotton-seed meal, wool waste, cotton hulls, ground bone and tankage, bone, acid phosphate, dissolved boneblack, bone ash, South Carolina rock, and other mineral phosphates, Odorless Phosphate (slag), muriate of potash, kainit, sulphate of potash, sulphate of potash and magnesia, ashes, factory-mixed fertilizers, and home mixtures.

The price of complete fertilizers declined from 1885 to 1893, but this decline "was not accompanied by a corresponding decrease in the absolute amounts of plant food delivered to consumers." The use of fertilizers in the State is increasing, their cost amounting to $1,641,615 in 1893 as against $1,509,921 the previous year.

"Farmers can make mixtures which are equal to the best manufactured brands and superior to the average—first, in mechanical condition; second, in concentration; third, in quality, and fourth, in point of cost.

"Many farmers' clubs and granges are now buying their [fertilizing materials in bulk and doing their own mixing] and several transactions by such organizations this year, which involved the purchase of 700 tons of materials, were carefully studied by the station in order to show the actual gains that were made. The 700 tons cost $20,790, or on an average at the rate of 14.9 cts. per pound for nitrogen, 5.7 cts. per pound for available phosphoric acid, and 4 cts. per pound for potash. The average cost per pound of these fertilizer elements, bought in mixed goods from dealers, is this year 24.8 cts. for nitrogen, 9.4 cts. for available phosphoric acid, and 6.7 cts. for potash. The total cost of the amounts of constituents contained in the 700 tons would, on this basis, have been $34,489, or a difference in favor of the former method of $13,699, on a transaction which represents less than one thirtieth of the total annual consumption in the State. This study also showed that if the average manufactured fertilizer had contained as much plant food as was contained in the mixtures made from the 700 tons of materials purchased, the total amount used in 1892 would have been contained in 23,172 tons, instead of 33,821 tons, or a difference of 10,649 tons. A comparison of the selling price and valuation of the mixed goods examined this year shows further that the cost to the farmer for mixing, bagging, and selling averaged $9.70 per ton, or a total for the 10,649 tons of $93,295. That is, the labor connected with the handling and selling of 10,000 tons of absolutely worthless materials amounted to nearly $100,000.

"In buying manufacturers' mixtures distinct advantages in quality and cost are secured when bought direct from the manufacturers instead of from local agents."

Fertilizers, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 40–43*).—A summary of Bulletin 29 of the station (E. S. R., 6, p. 395).

The use of human excrement as a fertilizer, J. H. VOGEL (*Deut. landw. Presse, 22 (1895), No. 8, pp. 66, 67; No. 10, pp. 83, 84; No. 11, p. 92*).

The cause of the relatively incomplete utilization of the nitrogen of stable manure, P. WAGNER (*Deut. landw. Presse, 22 (1895), No. 11, pp. 91, 92; No. 12, pp. 98, 99, figs. 15*).

The loss in the fertilizing value of stable manure when exposed, G. CATANI (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 60–67*).

Management of farmyard manure (*Agl. Jour. Cape Colony, 8 (1895), No. 2, p. 40*).—General comment, including a brief description of methods pursued by the Longerenong Agricultural College, Australia.

Experiments in conserving stable manure by covering it with earth, A. GRILLI (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 68–74*).

Practical experience concerning the effect of stable manure in the light of recent investigations, P. WAGNER (*Deut. landw. Presse, 22 (1895), No. 14, p. 123*).

The nitrogenous fertilizers of commerce, C. DUSSERRE (*Chron. Agr., 8 (1895), No. 5, pp. 102–105*).—Brief general statements.

A study of the agricultural value of the phosphate of alumina of Grand-Connétable, A. ANDOUARD (*Compt. Rend., 120 (1895), No. 6, pp. 337–339*).—This phosphate was compared with other mineral phosphates, including Algerian, Somme, South Carolina, and Florida phosphates in pot experiments on balsam, flax, white mustard, and buckwheat, with results indicating that it may be profitably used in untreated condition. More complete field experiments are stated to be in progress.

On the agricultural value of the phosphates of alumina—remarks on the previous note, A. GAUTIER (*Compt. Rend., 120 (1895), No. 7, pp. 356–358*).—Recounts 3 years' field experiments on a large scale with Redonda and Connétable (Guana) phosphates, which confirm Andouard's conclusions as to the high assimilability of such phosphates, but it is maintained that this high assimilability is confined to those phosphates indirectly resulting from fermentation of nitrogenous matter, and generally in an amorphous or indistinctly or partially crystallized condition.

Preparation of a fertilizing material containing citrate-soluble phosphoric acid, O. PEIPER (*Chem. Ztg., 19 (1895), No. 11, p. 221*).—A patented process in which fine ground iron or aluminium phosphate is stirred into a hot solution of lime in soda or potash.

Fertilizers and gypsum (*California Sta. Rpt. 1893 and 1894, pp. 192–200*).—Analyses of 3 samples of fertilizers and 37 samples of gypsum or gypseous earths, with accounts of gypsum mines located near Mendota, Fresno County, and in San Benito County, California.

Manure in its relations to plant evaporation, C. D. REED (*Amer. Agr., (middle ed.), 1895, Feb. 23, p. 194*).

Analyses of commercial fertilizers, T. J. EDGE and W. FREAR (*Pennsylvania State Bd. Agr. Bul., Jan. 1, 1895, pp. 24*).—Text of the act regulating the manufacture and sale of commercial fertilizers in Pennsylvania; schedule of trade value of fertilizing ingredients, with notes on valuation; and tabulated analyses and valuations of 342 samples of fertilizing materials, including ground bone, acid phosphate, and mixed fertilizers.

FIELD CROPS.

Experiments with corn, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 18–23*).—These consisted of variety tests and fertilizer experiments. The largest yields in 1889 were made by Mosby Prolific, St. Charles Parish, White Dent, Improved Leaming, Welborn Conscience, and Piasa King; in 1890 by Mosby Prolific, Cock Prolific, Minter Prolific, Bailey, Mammoth Surprise, and Evans. In 1889, 1890, and 1892 the white varieties yielded more than the yellow varieties.

"As a rule the yellow varieties make larger ears, but we have found very few which average more than 1 ear to the stalk. Of those varieties noted as being the best 6, the white varieties averaged 127 ears to 100 stalks, while the yellow varieties bore only 105 ears to 100 stalks. . . . It is probably true that the yellow varieties stand up better in the field and are less liable to rot when left in the field until late in the season."

The results of fertilizer tests varied according to the soil on which the crop was grown. In 1889, on a very heavy dry clay soil, 500 lbs. of fresh cotton seed gave the largest yield. In 1890 and in 1891 the most profitable fertilizer was a compost of stable manure, cotton seed, acid phosphate, and kainit. In 1892, on a heavy red clay soil from which the surface soil had been badly washed and which had given a light crop of lespedeza the preceding year, 240 lbs. of cotton-hull ashes gave the largest yield, an increase of 123 per cent over the yield of the unfertilized plats. In 1893, on a heavy soil which had grown a crop of cowpeas in the preceding year, 500 lbs. of kainit to the acre more than doubled the yield of the unfertilized plat. Results of fertilizer tests at Holly Springs are also stated.

"From the work which has been done both at Holly Springs and at the home station, there seems to be no great difference between the fertilizers required for corn and those which are most needed for cotton. The first essential for both is evidently an abundant supply of humus, which can be provided most economically by the plowing under of green leguminous crops, but which may be supplied in stable manure, cotton seed, or [cotton-seed] meal With a soil rich in humus and in lime, potash should be used liberally, while but little phosphoric acid and no nitrogen need be given. Where lime is deficient both potash and phosphoric acid should be used, and if deficient in humus, nitrogen should also be applied in the form of [cotton-seed] meal for sandy soils and [cotton] seed for heavy clay uplands."

Experiments with cotton, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 6–17*).

Synopsis.—The results of 5 years' work in fertilizer tests in 3 localities and of variety tests are summarized. Fertilizer tests indicate that the soil of the station farm is especially benefited by manures or fertilizers rich in organic matter and potash. At the Holly Springs Substation results were not decisive. At the Lake Substation phosphoric acid proved superior to potash. The value of the crop for the 6 varieties affording the greatest value per acre (in lint and seed) in each of the 5 years of the experiment are given and the results for 1893 are tabulated in full.

Fertilizer experiments (pp. 6–13).—At the station in 1889 200 lbs. of kainit per acre proved the most effective and economical fertilizer. In 1890, on a similar soil, the Furman compost (containing 750 lbs. of stable manure, 750 lbs. of cotton seed, 333 lbs. of acid phosphate, and 167 lbs. of kainit per ton) proved most economical, though sulphate of potash afforded nearly the same yield.

In 1891, on an exhausted, dry, yellow clay hill the best results followed the use of 1,000 lbs. of cotton seed per acre; on a heavy red clay soil 15 tons per acre of stable manure produced the largest yield, while kainit gave the cheapest increase in crop; on an exhausted yellow loam the substitution of kainit for the acid phosphate in the Furman compost largely increased the yield and cheapened the cost of production both in 1891 and 1892. Again in 1893 a compost rich in potash gave a larger yield than one relatively poor in this ingredient and rich in phosphoric acid; 500 lbs. of kainit alone increased the yield by 222 lbs. of seed cotton per acre, while 250 lbs. of acid phosphate alone produced no notable effect.

> "All of the soil used for this work at the home station has been rich in lime and very poor in humus. From the work which has been done here during the last 5 years, the results have been quite uniform, and indicate very plainly that for such soils the first work in restoration must be the providing of a liberal supply of humus, which may come from either stable manure, cotton seed, or the plowing under of green leguminous crops, and that any additional fertilizers used should be rich in potash, though they need contain but little phosphoric acid."

At Holly Springs results for the different years do not accord.

> "So far as can be seen from the work done, the upland clay soils of that region will be fertilized most economically by the use of either [cotton seed] meal or compost to furnish vegetable matter and nitrogen, and to these should be added both phosphoric acid and potash, more of the latter than the former being needed. For the sandy valley lands cotton-seed meal seems the best foundation for the fertilizer, and to that should be added more phosphoric acid than potash, though both are needed."

At Lake, in the pine woods region, the average yields of seed cotton per acre on a sandy clay loam containing but little lime were as follows:

Average yields per acre of seed cotton for 3 years.

Fertilizer.	Yield of seed cotton.
	Pounds.
Nothing	614
35 bu. cotton seed, or 200 lbs. cotton-seed meal 200 lbs. kainit	846
35 bu. cotton seed, or 200 lbs. cotton-seed meal 200 lbs. acid phosphate	1,253
35 bu. cotton seed, or 200 lbs. cotton-seed meal 200 lbs. acid phosphate 200 lbs. kainit	1,105
50 bu. cotton seed 400 lbs. acid phosphate 200 lbs. cotton-hull ashes	1,169
100 bu. cotton seed 200 lbs. acid phosphate 200 lbs. cotton-hull ashes (2 years)	1,249

Variety tests (pp. 13–17).—The most profitable varieties were as follows:

Varieties of cotton producing the greatest value per acre in lint and seed.

Bates Big Boll.

"Of the so-called varieties we have a very large number, but of what may be called 'types' there are but 4 which are so distinct as to be generally recognized. These are the Cluster and Long-Limbed, the Long Staple and the Short Staple, and in each of those we have many inconstant 'varieties' which change their character with every change of soil.

"In comparing varieties of the 'long-limbed' and the 'cluster' types we have found no constant differences in the yields, though the cluster varieties have always matured later than have some of the long-limbed sorts; while a long-limbed variety which produces unusually large bolls always matures later than do most of the cluster varieties. . . .

"With nearly 100 so-called varieties which have been tested, the average yield of the short-staple sorts has been nearly double that of the long staples."

Neither Japanese, Peruvian, nor Egyptian varieties proved valuable on the station farm.

Cowpeas, H. N. STARNES (*Georgia Sta. Bul. 26, pp. 163–185, figs. 85*).—Experiments conducted on cowpeas in 1894 consisted of fertilizer tests, variety tests, and a comparison of badly discolored, slightly discolored, and perfect seed. The main purpose of the fertilizer experiment was to determine the relative values of Florida soft phosphate and superphosphate, alone and in different combinations. The following is the author's summary:

"(1) It is money thrown away to apply any form of nitrogenous fertilizer to the cowpea. . . .

"(2) The use of potash salts in large quantities is unprofitable, and even in small quantities will not pay in the oak and hickory region of the South. On other than oak and hickory lands small doses may prove profitable in conjunction with acid phosphate, and the longer the land has been in cultivation the greater becomes this probability, even in the oak and hickory belt.

"(3) Heavy applications of any form or combination of fertilizers are unprofitable.

"(4) The moderate use of phosphates [alone] appears still to return the best results from an economical standpoint.

"(5) As between superphosphate (acid phosphate) and Florida soft phosphate (unacidulated ground rock) results indicate decided preference for the former, so far as the growth of vines is concerned.

"(6) There is less difference observable between the two in the formation of peas, though superphosphate still appears to be preferable.

"(7) The finely pulverized condition of soft phosphate is a great objection to its use, rendering it extremely difficult to handle without loss.

"(8) There is not a sufficient difference in price between the two forms of phosphate to render soft phosphate at present an active competitor to acid phosphate, unless the ascertained results were more emphatic in its favor. . . .

"(9) The quantity of acid phosphate which may be safely depended upon differs, of course, with the character of the land. The better the soil (in its mechanical composition as well as in its chemical contents) the greater the amount that may be profitably used. A range of from 200 to 400 lbs. per acre will probably cover all contingencies."

The 46 varieties grown at the station in 1894 are described and figured. Cowpeas are classified according to the form of the pea, habit of growth, time of maturity, color of pod, color of peas, size of pod, and size of peas. Two forms of cowpea are described, the Crowder and Kidney types. In habit of growth the varieties are classified as follows:

"*Trailing:* Conch, Red Eye, Williams Hybrid.

"*Recumbent:* Calico, Congo, Large Lady, Lilac Red Pod, New Era, Pony, Red Crowder, Red Ripper, Saddleback, Small Lady, Smith No. 7, Smith No. 9, Smith No. 14, Speckled Crowder, Sugar Crowder, Vacuum, White, White Brown Hull, White Crowder, White Giant.

"*Semi-Recumbent:* Black, Black Eye, Blue Hull, Chocolate, Constitution, Everlasting, Forage or Shinny, Granite, Gourd, Mathews, Mush, Purple Hull Crowder, Redding, Red Yellow Hull, Rice, Shrimp, Smith No. 15, Taylor Prolific.

"*Erect:* Clay, Coffee, Quadroon, Red, Unknown, Whippoorwill, Wonderful."

In time of maturity the classification is as follows:

"*Very Early:* Chocolate, Congo, New Era, Vacuum, White Giant.

"*Early:* Granite, Red Crowder, Red Eye, Red Yellow Hull, Saddleback, Smith No. 9, Whippoorwill.

"*Medium:* Coffee, Large Lady, Lilac Red Pod, Mush, Pony, Small Lady, Smith No. 7, Smith No. 15, White, White Brown Hull.

"*Late:* Black Eye, Everlasting, White Crowder, Williams Hybrid.

"*Very Late:* Black, Blue Hull, Calico, Clay, Conch, Forage or Shinny, Gourd, Mathews, Purple Hull Crowder, Quadroon, Red, Redding, Red Ripper, Rice, Shrimp, Smith No. 14, Speckled Crowder, Sugar Crowder, Taylor Prolific, Unknown, Wonderful."

The yields of vines and of peas for each variety are tabulated.

The following are the author's conclusions:

"(1) The earliest cowpea, and hence the variety best adapted to high latitudes, is the New Era; this matures in a little more than 60 days from time of planting. Other very early varieties are Congo, White Giant, Chocolate, and Vacuum.

"(2) The heaviest yielder of vines is Red Ripper, followed closely by Forage or Shinny, Black, and Unknown.

"(3) The heaviest producers of peas are Unknown, Calico, Clay, and White Brown Hull.

"(4) The yield of peas, as a rule, though not invariably, parallels the yield of vines.

"(5) For hay, the erect varieties are preferable to those of a recumbent habit, since the mower cuts them all. The best of the erect varieties are the Unknown, Clay, and Whippoorwill.

"(6) Where a dense mass of vines is wanted to remain all winter on the ground, Calico, Gourd, Black, and Constitution are preferable.

"(7) The best table peas are Sugar Crowder, White Crowder, Mush, Large Lady, Small Lady, and Rice.

"(8) The best stock pea for field grazing of either cattle or hogs is the Black. It will remain in ground all winter without injury. Everlasting, Red, and Red Ripper are also good.

"(9) For an 'all purpose' pea the Unknown leads the list. Clay, however, closely contests first place. Unknown and Wonderful are identical."

Neither the germinating power nor the subsequent growth was lessened by discoloration of the peas used as seed.

Experiments with cowpeas and crimson clover, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 7–13*).—Silage made of cowpea vines was relished by cows and largely increased the flow of milk. In a fertilizer test 160 lbs. of muriate of potash per acre doubled the yield of cowpea vines; nitrate of soda largely increased the yield, but acid phosphate exercised no marked effect. The varieties Unknown and

Conch failed to ripen seed, but the Black cowpea yielded at the rate of 25 bu. of seed per acre when fertilized with muriate of potash. Heavy seeding of cowpeas, by using all the tubes of a grain drill, is recommended.

Italian rye grass sown with crimson clover produced sufficient seed after the first cutting to reseed the land.

Crimson clover straw moistened with water which had been sweetened with low-grade molasses was successfully used as a substitute for hay in feeding cows.

The yield of wheat was largely increased by plowing under a crop of crimson clover in May and a crop of cowpeas in September.

Experiments with oats, G. LIEBSCHER (*Jahrb. deut. landw. Ges., 9 (1894), pp. 453–510*).—These experiments with varieties extended over 5 years and were conducted in numerous localities in Germany. On averaging the yields for 5 years of a number of varieties grown on different classes of soils, it was found that whenever a variety was productive as compared with other varieties on one class of soil it was relatively productive on all other soils. The author states that there is no foundation for the claim that one variety ranks high in yield on one class of soils but low on another.

However, when a variety was originated and the seed grown on one kind of soil it proved more productive (relative to other varieties) on similar soil than on that of a different character. On light soil seed grown on light soil was more productive than seed grown on heavy soil. Seed grown on heavy soil showed a preference for heavy soil.

Varieties originating in a region with a continental climate were most successfully grown in a similar climate; those originating in a marine climate were most productive under similar climatic conditions.

As in previous years varieties did not differ in their percentages of nitrogen and phosphoric acid; these percentages, however, were influenced by the character of the soil on which the crop was grown, by the fertilizers used, and by the weather.

Peanuts, culture and uses, R. B. HANDY (*U. S. Dept. Agr., Farmers' Bul. 25, pp. 24*).—The following subjects are treated: Description and history, composition, with analyses of food and fertilizing constituents in different parts of the plant, varieties, climate and soil adapted to the peanut, manuring, preparation of the land, selection of seed, planting, tillage, harvesting, and uses. A crop of 60 bu. (1,380 lbs.) of peanuts, together with 2,000 lbs. of hay, total 3,380 lbs., is estimated to contain 84.71 lbs. of nitrogen, 14.80 lbs. of phosphoric acid, 32.30 lbs. of potash, and 46.30 lbs. of lime. If the soil for peanuts does not contain lime this should be applied as a fertilizer, together with phosphoric acid and potash. A rotation suggested for peanuts is as follows: Peanuts, followed in the fall by winter rye or oats, and the next summer the land sown to crimson clover, to be followed the next year by peanuts again, so that every other year peanuts will be the crop. Care in the selection of seed is urged. Analyses show that peanut hay and peanut cake have a high feeding value.

Originating varieties of potatoes, G. LIEBSCHER (*Jahrb. deut. landw. Ges.*, *9* (*1894*), *pp. 303–318*).—The theory and history of plant breeding are discussed at some length. Modern potato breeders select as parents 2 varieties which in most qualities bear close resemblance to each other, avoiding the use of opposites. Their aim is to secure as much similarity as possible in most of the qualities of the parents, attempting to fix one characteristic at a time.

This is somewhat in contrast with earlier practice, in which varieties differing widely were crossed. As an instance of the advantages of the modern method, which gives a smaller amount of variation in the seedlings produced, one potato breeder stated that under the earlier system he sometimes grew annually several thousand seedlings, only 1 per cent of which was worthy of a second year's trial, while by crossing varieties similar in most qualities as many were secured by growing only 300 to 500 seedlings, of which 50 to 70 per cent usually proved worthy of further trial.

Breeders no longer expect to get certain qualities from the female parent and certain others from the male.

The interrelation of different qualities is not well known, but it has been noted that a variety having few thick stalks affords only a small number of tubers, which are large; one having numerous slender stalks bears numerous tubers, which naturally remain small. Violet-colored stalks indicate colored tubers; white flowers generally, but not always, accompany white tubers. Early ripening and resistance to disease are not generally found together. A large production of true seed is believed to go hand in hand with a small production of tubers.

Whether or not the time of ripening of a variety can be changed by selection and by varying the time of planting is a mooted question among potato breeders.

In pollenizing varieties artificially the stamens should be removed from the female parent with fine pinchers just as the bloom opens, and the flower inclosed in a paper or gauze bag. The proper stage for applying the pollen is indicated by the moist appearance of the stigma. The pollen from the desired variety should be dusted on the stigma on 2 or 3 successive days, so as to make sure of fertilization. The bag is removed as soon as the stigma dries and the bloom withers.

The seeds are washed out from the ripe seed balls, dried, and at the proper season sown shallow under glass. The seedlings are first transplanted in a hotbed, and later the strongest plants are placed in a rich bed out of doors. The distance between the seedlings varies from 12 by 12 in. to 26 by 26 in. The old rule that in the first year the seedlings should produce tubers of the size of a hazelnut, in the second year of walnut size, and normal tubers not before the third year is no longer applicable. In one instance a seedling produced the first year tubers weighing about 200 gm. (over 7 oz.).

The tubers produced by each plant are kept separate. Those of the best plants are used for propagation the following year, the distance allowed by some breeders in the second year being only 25.6 by 12.8 in., by others 40 by 40 in. Close planting is sometimes advocated as affording the conditions under which the plant is in future to be grown on a large scale. Wide planting permits of easier observation of each plant, is less subject to errors arising from an irregular stand, and is the method favored by the author. The best stocks are planted in the third year on areas of 20, 50, or 100 square meters, are given the usual field culture, and compared in yield and qualities with well-known varieties. It is usually 5 years before there is obtained a type so fixed and valuable as to serve for future crossing and to deserve a name.

Fertilizer experiments on Irish potatoes (*New Jersey Stas. Rpt. 1893, pp. 120-124*).—Experiments on twentieth-acre plats were conducted in Gloucester County on a sandy, well-drained loam of medium fertility, and in Somerset County on a gravelly clay loam with good drainage. Three hundred and twenty pounds of boneblack, 160 lbs. of muriate of potash, 240 lbs. of sulphate of potash, and 200 lbs. of nitrate of soda were used in various combinations. Stable manure was used alone at the rate of 20 tons per acre, and at the rate of 10 tons per acre in combination with half the above amounts of commercial fertilizers. On 2 plats the quantity of commercial fertilizers was 50 per cent greater than that indicated above. The following table gives the cost of fertilizers per acre, the value at 75 cts. per bushel of salable crop after deducting cost of fertilizers, and the value of the increase after deducting cost of fertilizers:

Financial results per acre from the use of stable manure and chemical fertilizers on Irish potatoes.

	Cost of fertilizer.	Gloucester County.		Somerset County.	
		Net value of crop.	Net value of increased crop.	Net value of crop.	Net value of increased crop.
Unfertilized	....	$31.50	....	$54.38	....
Stable manure alone	$10.00	71.01	$39.51	38.75	—$15.63
Stable manure and chemical manure	39.26	84.65	53.15	46.14	— 8.24
Complete chemical manures alone	15.10	71.24	39.74	82.12	27.74

In the first experiment both chemical fertilizers and stable manure were used with profit; in the second experiment only chemical fertilizers returned a profit.

Ramie, W. C. STUBBS (*Louisiana Stas. Bul. 32, pp. 1127–1146*).—The possibilities of ramie culture, the character of the ramie plant and fiber, the draft made on the soil fertility by ramie, and machines for preparing ramie fiber are treated at length. The data relative to the composition and fertilizer requirements are quoted from Bulletin 94 of the California Station (E. S. R., 3, p. 371).

The ramie plant is perennial and yields from 8 to 15 tons of green unstripped stalks per acre. Ramie may be decorticated either when the stalks are green or dry. In the humid climate of Louisiana the fiber should be prepared from green stalks. Some machines are adapted to working ramie dry, others to working it green, and a few claim to work the stalks either green or dry.

In the fall and winter of 1894 a committee tested at the station 3 decorticating machines. One of the machines decorticated 1,000 lbs. of freshly cut unstripped stalks in 1 hour 5½ minutes, and the fiber produced when dried weighed 56 lbs. In another test this machine decorticated 500 lbs. of green unstripped stalks in 24 minutes, yielding 30½ lbs. of dry fiber.

Another machine decorticated 112 lbs. of dried ramie stalks without leaves in 2 hours 11 minutes, during which time the machine was in actual operation only 52¾ minutes; the product was 30 lbs. of fiber. In another trial 380 lbs. of green ramie stalks, stripped (equal to 655 lbs. of unstripped stalks), were decorticated with saturation in 50 minutes; the product was 25¼ lbs. of dry fiber. In other tests, green unstripped stalks were decorticated at the rate of 825.9 and 1,200 lbs. per hour.

A smaller machine decorticated dry ramie stalks at the rate of 322 lbs., and green unstripped stalks at the rate of 960 lbs. per hour.

One of the machines delivered the fiber in a somewhat tangled condition and left a piece of adherent wood at the end of each fiber. Another machine required too much power. The outlook for obtaining a successful ramie machine is regarded as promising.

Fertilizer experiments with salt grass (*New Jersey Stas. Rpt. 1893, p. 137*).—Nitrate of soda alone and in combination with superphosphates and muriate of potash failed to increase the yield of the salt grass (*Juncus geraldi*).

Experiments with wheat, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 23–25*).—Several varieties of English and French wheat were grown at the station. The English varieties failed; the French varieties, White Naples and Rieti, proved valuable. The average yield for 3 years of wheat grown on prairie or creek bottom soil was 21.3 bu. per acre. A crop of wheat and of corn was grown on the same field within 12 months, one variety of wheat yielding 24.1 bu. per acre, and the corn yielding 26 bu. per acre.

The best fertilizer for wheat on a gray loam, somewhat sandy, was a mixture of 400 lbs. of acid phosphate, 250 lbs. of kainit, and 400 lbs. of castor pomace per acre. This mixture increased the yield 131 per cent.

Wheat, barley, oats, rye, and spelt, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 393–397*).—Tabulated data give the time of ripening and of cutting, length of straw and ear, yield of grain and of straw, and brief notes on the character of growth and grain for 64 varieties of wheat, 17 of barley, 12 of oats, 5 of rye, and 6 of spelt. The largest yield of wheat was made by California Spring wheat, followed by Clawson, Imperial Circassian, and Jonquil. The largest yields of rye were made by Department of Agriculture No 2 and Department of Agriculture No. 6. The most productive variety of oats was White Wonder. Excelsior Winter and St. John's Day rye gave the largest yields of grain, Spanish Double-Bearing and St. John's Day the largest yields of straw. The most productive variety of spelt was White Silesian.

A rotation for dairy farms (*New Jersey Stas. Rpt. 1893, pp. 151, 152*).—A rotation intended to furnish a continuous supply of green fodder was begun in 1893, and the plan was as follows: First year, field corn, seeded to crimson clover in July or August; second year, crimson clover, followed by fodder corn and the land seeded to rye after the corn; third year, rye fodder, followed by oats and peas, seeded to red clover and timothy; fourth year, hay.

Species of agave and their industrial utility, R. ROLAND-GOSSELIN (*Bul. Jour. Soc. Cent. Agr. Alpes-Maritimes, 35 (1895), No. 1, pp. 17–21*).

German and American red clover, O. BURCHARD (*Mitt. deut. landw. Ges., 1895, No. 2, pp. 15–17*).

Crimson clover (*New Jersey Stas. Rpt. 1893, pp. 153–155*).—Brief statements concerning the crops grown on 3 farms in different sections of the State.

Corn, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 61–67*).—A reprint from Bulletin 27 of the station (E. S. R., 6, p. 215).

The chemistry of the cotton plant (*Mississippi Sta. Rpt. 1893, pp. 50–52*).—A brief report of work already published in Technical Bulletin 1 of the station (E. S. R., 4, p. 719).

Cotton, potatoes, and vegetables, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 392, 393*).—Several varieties of cotton and 16 of potatoes were grown. Neither potatoes, carrots, nor turnips proved successful. Other plants grown were watermelons, cucumbers, gourds, snap beans, garden peas, and tomatoes. Tomato vines, protected late in autumn "with lath frames," were kept alive and growing through frosts as low as 26° F., but a temperature of 19° killed the vines.

Cotton, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 70–72*).—A reprint from Bulletin 27 of the station (E. S. R., 6, p. 215).

Preparation of soil for cotton, C. L. NEWMAN (*Arkansas Sta. Rpt. 1894, pp. 100–103*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 402).

Cowpea hay, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 73–79*).—A reprint from Bulletin 27 of the station (E. S. R., 6, p. 215).

Flax, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 27, 28*).—Several varieties of flax were grown at the station, but the yield was too small for the crop to be profitable.

Forage plants, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 79–83*).—A reprint from Bulletin 27 of the station (E. S. R., 6, p. 215).

Experiments with grass and clover, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 127–136*).—A reprint from Bulletin 29 of the station (E. S. R., 6, p. 531).

Grasses and forage plants, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 28–30*).—Conclusions are given drawn from experiments detailed in Bulletin 20 of the station (E. S. R., 4, p. 248) and Farmers' Bulletin 18 of the U. S. Department of Agriculture (E. S. R., 6, p. 294).

Grasses and forage plants, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, p. 393*).—A number of the forage plants failed to germinate and others were killed by drought and north winds. The following species were successfully grown: Japanese rye grass, Hungarian brome grass, *Digitaria sanguinalis*, velvet grass, perennial rye grass, redtop, teosinte, *Phalaris media*, canary grass (*P. canariensis*), *Lotus tetragonalobus* and *Melilotus alba*.

Hay from barley, wheat, and oats, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 374, 375*).—Tabulated data and notes on the yield of hay at the Foothills Substation.

A comparison of black Siberian lupines with other species, C. SCHRAPE (*Fühling's landw. Ztg., 44 (1895), No. 3, pp. 80–82*).—This excelled in yield and contained a smaller amount of alkaloids than other species.

Black medick (Medicago lupulina), E. WILCZEK (*Chron. Agr. Cant. Vaud, 8 (1895), No. 4, pp. 82–84*).—At Zurich black medick from Germany gave a larger yield of forage, produced larger leaves and seeds, and proved hardier, but was later in reaching maturity than seed from Germany.

Experiments with flat pea, sachaline, and Trifolium pannonicum, E. WILCZEK (*Chron. Agr. Cant. Vaud, 8 (1895), No. 2, pp. 24, 25*).—Ordinary meadow mixtures exceeded in productiveness flat pea aged 1, 2, and 3 years; on dry, rocky declivities the latter proved valuable. Sachaline is not commended. *Trifolium pannonicum* is hardy and productive, but makes only a slow growth.

On the composition of certain French and foreign oats of the crops of 1893, BALLAND (*Compt. Rend., 120 (1895), No. 9, pp. 502–504*).

The origin of the potato (*Rev. Scientif., 3 (1895), ser. 4, No. 8, p. 258*).

Variety tests of potatoes, H. PETTWEILER (*Deut. landw. Presse, 22 (1895), No. 12, pp. 102, 103*).

The best varieties of potatoes, VON ECKENBRECHER (*Jahrb. deut. landw. Ges., 9 (1894), pp. 290–303*).—A report on prize varieties.

The influence of the removal of the lateral eyes of the seed tubers upon the growth and productiveness of the potato plant, E. WOLLNY (*Forsch. Geb. agr. Phys., 17 (1894), No. 5, pp. 461–473*).

The second crop of Irish potatoes, C. L. NEWMAN (*Arkansas Sta. Rpt. 1894, pp. 96–100*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 409).

Potato culture, (*Amer. Agr. (middle ed.), 1895, Feb. 16, Feb. 23, Mar. 2, Mar. 9, Mar. 16, pp. 164, 196, 221, 252, 281*).—This is a series of articles based upon the results of a "potato contest" in 1889 and 1890, and giving general conclusions relative to soil, preparation, fertilization, seed potatoes, varieties, and cultivation.

Experiments with rye, C. L. NEWMAN (*Arkansas Sta. Rpt. 1894, pp. 90–93*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 411).

Sugar beets (*New Jersey Stas. Rpt. 1893, pp. 155–157*).—A brief statement of the method of cultivating sugar beets in Cape May County, and analyses of 8 varieties of sugar beets.

The sugar content of sugar beets which have developed seed stalks, G. DE MARNEFFE and O. CASTEELS (*Ingén. Agr. Gembloux, 5 (1895), No. 8, pp. 351–354*).

Effect of manuring beets and other roots with potash salts (*Deut. landw. Presse, 22 (1895), No. 9, pp. 74, 75*).

Sugar beets and sugar cane, M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 218, 219*).—Analyses of sugar beets from 4 localities and of 1 sample of sugar cane are tabulated.

The nitrogen content of sugar cane, LOOKEREN-CAMPAGNE (*Deut. Zuckerind., 20 (1895), p. 22; abs. in Chem. Ztg., 19 (1895), No. 10, p. 28*).

Sorghum and sugar cane, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 25, 26*).—Brief notes on varieties of sorghum grown at the station in 1889 and 1890, and on a fertilizer test for sugar cane.

Sorghum, perennial cotton, sugar cane, and cereals, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 419, 420*).—Brief references are made to all of these crops cultivated at the Southern California Substation. Perennial or Catacaos cotton bloomed in November and December and was killed to the root by light frosts. Reference is made to the special value of a tract of moist land belonging to the substation and a list of grasses sown in 1893–'94 is given.

Notes on culture of tobacco in Virginia, R. H. GAINES (*Southern Planter, 56 (1895), No. 3, pp. 107, 108*).—Continued.

Fertilizers for tobacco, H. J. PATTERSON (*Southern Planter, 56 (1895), No. 3, pp. 109, 110*).—A summary of results of experiments, particularly those of the Maryland station, already reported in Bulletin 26 of that station (E. S. R., 6, p. 209).

Wheat, barley, and sorghum, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 410, 411*).—The yields of 13 varieties of wheat are tabulated. Himalaya barley, an early and productive variety tested at the station, is recommended as a profitable variety for hog raisers. Nepaul barley, which is beardless, has large and heavy heads and palatable straw and is highly recommended for hay. The report contains a brief note on sorghum.

Fertilizer experiments with wheat, A. PASQUINALI and A. SINTONI (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 27–42*).

Varieties of winter wheat, F. HEINE (*Deut. landw. Presse, 22 (1895), No. 6, pp. 47, 48*).

Experiments with wheat, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 115–126*).—A reprint from Bulletin 29 of the station (E. S. R., 6, p. 538).

Late crops for overflow land, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 53–61*).—A reprint from Bulletin 27 of the station (E. S. R., 6, p. 212).

Rotation experiments, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 68–70*).—A reprint from Bulletin 27 of the station (E. S. R., 6, p. 217).

HORTICULTURE.

Electro-horticulture, F. W. RANE (*West Virginia Sta. Bul. 37, pp. 27, figs. 9*).—Detailed notes on experiments for testing the effect of incandescent electric light on plants grown in greenhouses. Incandescent lamps were used in preference to arc lights even in opal globes, as giving a much steadier and cheaper light, casting no sharp shadows. The experiments were carried on during the seasons of 1892–'93 and 1893–'94, 3 greenhouses being used for the purpose. The light was furnished by one 16-candlepower lamp and by a cluster of 7 lamps of the same strength, which could be used in various combinations. Usually the light was turned on during the entire night. Lettuce, endive, beets, radishes, spinach, cauliflower, and various ornamental plants were selected to be used in the experiment, the choice being partially governed by those already tried under the arc light. The same varieties used were also planted in an ordinary greenhouse unlighted at night as a check.

Of lettuce the varieties Grand Rapids, Hanson, and Tennis Ball gave, respectively, one sixth, one fourth, and one eighth greater yield by weight in the lighted house than that grown without the aid of electricity. Spinach and cauliflower also made an improved growth in the lighted house, but beets and radishes made a smaller growth in both houses. In 1893–'94 peas and beans were also planted, and, while irregularities in subirrigation affected the results with the beans, the peas proved better in the lighted house. Radishes, on the contrary, this year were far better in the dark house, earlier, with smaller tops and larger roots; but it is believed that a greater amount of moisture in the dark house was an important element in the difference. Various potted ornamental plants blossomed earlier under light.

The experiments are given in detail and illustrated from photographs showing various plants at different stages of growth in both the light and dark houses.

A résumé is given of experiments with electric light elsewhere, especially those of L. H. Bailey at the Cornell Station.

The following summary is given:

"(1) The incandescent electric light has a marked effect upon greenhouse plants.

"(2) The light appears to be beneficial to some plants grown for foliage, such as lettuce. The lettuce was earlier, weighed more, and stood more erect.

"(3) Flowering plants blossomed earlier and continued in bloom longer under the light.

"(4) The light influences some plants, such as spinach and endive, to quickly run to seed, which is objectionable in forcing these plants for sale.

"(5) Proper watering appears to be more important with radishes, beans, and cuttings than improper watering and the electric light.

"(6) The stronger the candlepower the more marked the results, other conditions being the same.

"(7) Most plants tended toward a taller growth under the light.

"(8) It is doubtful whether the incandescent light can be used in the greenhouse from a practical and economic standpoint on other plants than lettuce and perhaps flowering plants, and at present prices it is a question if it will pay to employ it for even these.

"(9) There are many points about the incandescent electric light that appear to make it preferable to the arc light for greenhouse use."

Report of the horticulturist, M. H. BECKWITH (*Delaware Sta. Rpt. 1893, pp. 132–152*).—This contains remarks on the testing of tomatoes and strawberries, notes on raspberries, determination of the vitality of peach seed, and pollination of the peach.

Notes are given on 63 varieties of tomatoes and 94 of strawberries, with the dates of ripening, and in the case of the latter of blooming, also. In addition, special comparative notes are given for the majority of the varieties tested. The Older and a new seedling black raspberry were tested, as also the Japanese wineberry, which is considered very productive and of excellent quality.

In response to inquiries on the subject, the question of some method for determining the vitality of peach seeds, either by the appearance or some other means requiring less time than actual germination, was taken up, and suspicious seed and a circular letter were sent to a number of nurserymen believed to be authorities on the subject. The responses received from 14 correspondents are given, showing great variance of opinion. Plump, aromatic kernels are considered the freshest, but the germination test is regarded as the most reliable one.

In an experiment to test the self-pollenizing powers of different varieties of peaches, 493 unopened blossoms of 12 varieties were covered with paper bags during the blooming season, the number varying in the different varieties. Of these, 16 set fruit. The 4 varieties, Fox, Oldmixon, Smock, and Wager, set 1 fruit each, while Crawford Early set 2, and Moore Favorite, 10.

An experiment begun with cross-pollination of peaches in a private orchard was not satisfactorily reported upon and was therefore inconclusive.

Experiments with fertilizers on asparagus (*New Jersey Stas. Rpt. 1893, p. 146*).—Notes on the growing of the variety Barr Mammoth on 3 acres of sandy loam, manured with commercial fertilizers. The plants were set in 2½-ft. rows, and a mixture of nitrate of soda, ground bone, boneblack, superphosphate, and potash applied along the rows in April. In May a second application was made. The experiment is to determine the profits to be gained by the best cultivation and most careful manuring.

Fertilizer and canning test of sugar corn, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 21, 22*).—Notes on an inconclusive and unfinished investigation as to the best method of obtaining the largest possible crop of sugar corn of the most desirable quality and the largest possible tonnage of fodder in keeping with the crop of ears and its quality. The varieties Stowell Evergreen and Zig-Zag were employed in the experiment, in which 24 plats were manured with different combinations of fertilizers. At the close of the experiment a case of corn from each of the plats was packed in a cannery and tested by experts as to its commercial value. The experiment is to be resumed.

Sweet potatoes, H. N. STARNES (*Georgia Sta. Bul. 25, pp. 127–161, pl. 1, figs. 35*).

Synopsis.—Experiments conducted at the station in 1893 and 1894 consisted of a fertilizer test, ridge *vs.* level cultivation, pruning the vines, moving the vines, distance experiments, and tests of varieties. The results favored a fertilizer containing potash, cotton-seed meal, and either superphosphate or soft phosphate. Ridge cultivation proved better in 1893 and level cultivation in 1894. Pruning and moving the vines both reduced the yield. A distance of 18 in. between the plants gave the largest yield. The most productive variety was White St. Domingo. Directions for the culture and storage of sweet potatoes are given.

In both years complete fertilizers largely increased the yield. In 1893, 320 to 325 lbs. of kainit and 80 to 81 lbs. of muriate of potash gave practically as good results as larger quantities. In 1893 kainit proved slightly superior to muriate of potash, and cotton-seed meal to nitrate of soda. In 1894 when Florida soft phosphate was compared with acid phosphate the yields were practically identical with the 2 fertilizers. "This can only be accounted for by the assumption that the potato is decidedly indifferent to either."

In 1893 the difference in favor of ridge over level culture was 35.67 bu. per acre. In 1894 the difference in favor of level culture was 33.1 bu., the latter season being dry soon after the plants were set and during September. The variety Pumpkin Yam when undisturbed yielded 201.3 bu.; when pinched weekly to 2 ft. throughout the season, 104.9 bu.; when pinched weekly after September 1 to 2 ft., 50.1 bu.

When the vines were not allowed to root the yield was 156.3 bu. per acre; when undisturbed the yield was 270.3 bu.

In 1893 at distances of 12, 24, and 30 in. between the plants in the row the yields were respectively 267.62, 237.08, and 229.75 bu. per acre. When 2 slips were inserted together at distances of 18 in. the yield was greater than when 1 slip was used either 18 or 9 in. apart. Thirty-three varieties are described and figured and their yields are tabulated. The largest yields were made by White St. Domingo, Shanghai or Clay, Boone White, and Hayman.

"The slit-leaf varieties are much the most productive. . . . They are also generally characterized by bright yellow flesh (when cooked), fineness of fiber, and delicacy of flavor. They are also as a rule excellent keepers. . . . The best potato in point of quality is the Georgia Yam, but it is unproductive. The best combination potato is probably the Tennessee Yam. It is of excellent quality and quite productive."

The composition of sweet potatoes, M. E. JAFFA and M. CURTIS (*California Sta. Rpt. 1893 and 1894, pp. 219–225*).—Seventeen varieties of sweet potatoes grown at the Pomona Substation were analyzed. The average results for the 17 varieties are given in the table below, which for comparison also contains the average results of 21 varieties grown at the Texas Station.

Analysis of sweet potatoes.

	California.	Texas.
	Per cent.	*Per cent.*
Water	70.00	70.00
Ash	1.08	1.14
Protein	1.86	2.41
Fat	.95	.99
Total sugar	5.71	6.81
Nitrogen free extract	23.60	24.00
Fiber	2.51	1.26

Sweet potatoes grown in Texas were richer in protein and sugar, while those grown in California contained a larger percentage of fiber. Of the 17 varieties grown in California, Bermuda contained the highest percentage of protein, 3.08 per cent, and Vineless the second largest percentage, 2.28. Barbadoes gave the largest content of total sugar, 11.55 per cent, and Red Nansemond the minimum. The varieties differed but slightly in the percentage of nitrogen-free extract.

Irish and sweet potatoes are compared with reference to their nutritive value. The potential energy in 1 lb. of Irish potatoes is calculated as 375; in 1 lb. of sweet potatoes, 537.

An analysis is given of the ash of sweet-potato roots, and on the basis of this analysis it is calculated that a crop of 5,000 lbs. of roots removes from the soil 31.4 lbs. of potash, 8.75 lbs. of phosphoric acid, and 15 lbs. of nitrogen.

Fertilizer experiments with sweet potatoes (*New Jersey Stas. Rpt. 1893, pp. 125–136*).—On a fertile soil in Gloucester County, manured the preceding year with 18 tons of barnyard manure, a sweet potato experiment was conducted on twentieth-acre plats in 1893. Mixed minerals (boneblack 120 lbs. and muriate of potash 160 lbs. per acre) were applied alone and in combination with 200 lbs. of nitrate of soda and 280 lbs. of dried blood per acre. Stable manure at the rate of 20 tons per acre was applied alone, and at the rate of 10 tons per acre in connection with half the quantity of commercial fertilizers indicated above. On 2 plats the amounts of commercial fertilizers were increased 50 per cent. The following table gives the yield of sweet potatoes, and the percentage of large potatoes in the crop:

Yield per acre of sweet potatoes differently fertilized.

	Total.	Large.	Small.	Large.
	Bushels.	*Bushels.*	*Bushels.*	*Per cent.*
Unfertilized	181.9	111.9	70.0	61.5
Minerals alone	235.2	170.6	64.6	72.5
Minerals and nitrate of soda	228.0	169.3	58.7	74.3
Minerals and dried blood	203.1	144.2	58.9	71.0
Barnyard manure	225.2	170.9	54.3	75.9

On this rich and well fertilized soil both nitrate of soda and dried blood proved unprofitable, the former, however, giving a yield superior to the latter. Increasing the commercial fertilizers by 50 per cent failed to increase the yield.

Reckoning large potatoes at 70 cts. per bushel and small potatoes at 50 cts., non-nitrogenous minerals alone gave a net profit of $30.68 per acre; non-nitrogenous minerals with nitrate of soda $26.37; non-nitrogenous minerals with dried blood $5.38; stable manure alone a net loss of $6.57; half rations of chemicals and manure a gain of $5.36, and whole rations of manure and chemicals a loss of $20.90.

The results of an experiment at Vineland, New Jersey, are also tabulated, although damage from drought prevented the drawing of conclusions.

Experiments with fertilizers on tomatoes (*New Jersey Stas. Rpt. 1893, pp. 103–119*).—Details and results of an experiment on the value of nitrate of soda in varying amounts, both alone and in different combinations with boneblack and muriate of potash. Twelve twentieth-acre plats were employed, 2 of them being left unfertilized and another treated with barnyard manure, as checks. To some of the plats all of the nitrate of soda was applied at once, and to others 2 applications were made, 3 weeks apart. The tomatoes matured more quickly and gave a greater proportion of early fruit on the plats receiving nitrate of soda. Other results were as follows:

"(1) Nitrate of soda is superior to both barnyard manure and mineral fertilizers alone.

"(2) Nitrate of soda alone is on the whole but slightly less effective than the complete manure.

"(3) When small quantities of nitrate are used the second application is advantageous; and

"(4) Large quantities (320 lbs. per acre) of nitrate are more effective than small quantities (160 lbs. per acre)."

Six tables are given, showing the features of the experiment in detail, the fertilizers applied, the dates of ripening, the relation of the early tomatoes to the entire crop, comparisons of the results from different fertilizers, ratios of the yield and market value, and other points.

Percentages of flesh, juice, and nutrients in the fresh edible portion of some California fruits, G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 271–274*).—Brief notes and tabulated data drawn from a number of analyses of different fruits. The fig is placed first in respect to protein, followed closely by the grape, and the nectarine last. The extremes of sugar content are found in fresh prunes and lemons. The results are shown in the accompanying table:

Amount and composition of the edible portion of some California fruits.

Fruits.	Number of analyses.	In whole fruit.		In edible portion.				
					Nutrients.			
		Flesh.	Juice, pressed.	Water.	Protein (N. x 6.25).	Fat, fiber, and carbohydrates, less sugar.	Sugar.	Mineral matters (ash).
		Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Oranges	13	73.0	52.00	88.30	.760	[1]3.840	7.10	....
Lemons[2]	22	71.0	45.50	....	....	....	1.63	....
French prunes	10	94.2	74.20	75.15	.944	3.641	19.70	.565
All prunes	20	94.2	74.20	80.20	.848	2.368	16.11	.474
Plums	3	95.2	71.00	78.40	.996	6.833	13.25	.524
Apricots	11	93.9	84.50	85.07	1.042	1.477	11.93	.477
Nectarines	1	93.4	85.00	82.90	.625	.855	15.13	.490
Figs	28	100.0	77.65	79.11	1.522	3.261	15.53	.577
Grapes	3	100.0	79.00	80.12	1.256	1.624	16.50	.500

[1] Contains the ash.

[2] The whole fruit yields: Water, 85.04 per cent; organic matter, 14.42 per cent; ash, 0.535 per cent; nitrogen, 0.152 per cent (corresponds to 0.95 per cent protein).

The ash analyses of various fruits reported in several previous bulletins are summarized, and a table is given showing the distribution of the various constituents in different fruits. Figs gave the most ash, 28 samples showing an average of 0.577 per cent, while the orange gave the least, 0.432 per cent. Potash was found to make up from one half to two thirds the whole ash, being the greatest, 63.83 per cent, in the prune, and least in oranges and lemons, 48 per cent. Soda was found to vary from 10.26 per cent in apricots to 1.76 per cent in lemons. The greatest variation was in lime, of which the ash of the lemon contained 29.87 per cent and that of the apricot 3.17 per cent. The percentage of phosphoric acid was found to be quite constant in the majority of the ashes, ranging from 11.9 per cent in lemons to 14 per cent in prunes. Grape ash, however, contained a high proportion of phosphoric acid, 21.24 per cent. The others, minor ingredients, are rated as unimportant and rather uniform. Silica, however, ranges from 0.65 per cent in the ash of citrus fruits to 5.2 per cent in that of apricots and grapes.

Fruit and fruit soils in arid and humid regions, E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 327–334*).—A discussion of the results of analyses of a number of soils from arid and humid regions and of fruits grown on these different soils. Tables are given showing the average of analyses of 466 humid and 313 arid soils, and the albuminoids, sugar, acid, and ash of various California fruits. In all the fruits examined, except the orange, the nutritive value is greater than in the analyses of the like European fruits, the increase in some instances being as much as 50 per cent. More extended and careful study of the subject is urged.

Analyses of bananas and banana soils from the Sandwich Islands, G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 275–279*).—Tabulated results of the analyses of 2 samples of soils from Honolulu, made to determine their requirements in the way of fertilizers for bananas. In addition, leaves and fresh fruit of the banana were analyzed to learn the ingredients drawn by them from the soil. It is calculated that an average 80-lb. bunch of bananas extracts 0.55 lb. of muriate of potash. Potash salts or kainit, and Chile saltpeter, dried blood, or some other nitrogenous fertilizer, and lime in the shape of coral sand, are recommended. As chlorin is needed a dressing of salt is also suggested.

Analyses of California oranges and lemons, G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 240–256*).—This comprises descriptive notes upon citrus fruits, tabulated proximate analyses of 32 samples of oranges, 18 of lemons, and 1 of pomelo, and is a continuation of the work presented in Bulletin 93 of the station (E. S. R., 3, p. 78). Tables are given showing the results of analyses in detail.

The Navel orange was found to be the largest, but the large proportion of rind, 28 per cent, gave it little if any advantage on account of its size over smaller oranges with thinner rinds. The varieties St. Michael and Tardive possessed only 20 per cent of rind. The Navel was also the driest orange, and the two others mentioned the juiciest, though closely followed by Medium Sweet, Malta Blood, and some seedlings. The King orange, of which but 3 specimens were analyzed, contained the most sugar, 13.17 per cent, being followed closely by seedlings and Navels. The largest amount of acid was found in a sample of Malta Blood, 2.04 per cent, and least in the Mandarin. The Navel also possessed little acid.

The lemons analyzed showed an average of 24.8 per cent rind, which is lower than was found the two years previous. The highest per cent of acid was 8.40 in Royal Messina, in which the juice was 55 per cent of the whole. The highest sugar content was 3.46 per cent, also in Royal Messina.

Analyses of the pomelo gave 2.7 per cent of citric acid and 9.5 per cent of sugar, cane sugar comprising 5 per cent.

The following table shows the average percentages of sugar and acid in various samples of several varieties of oranges analyzed in 1885 and 1891–'93:

Average percentages of sugar and acid.

Variety.	No. of samples.	Sugar.	Acid.
Navels	16	10.46	0.97
Seedlings	12	11.11	1.17
Mediterranean Sweets	8	9.55	1.75
St. Michaels	13	9.65	1.16
Malta Blood	6	10.10	1.41
Ruby Blood	3	11.08	1.51
King	3	13.17	1.49
Tardive (Valentia Late)	2	9.98	1.00

Hastened energy, a new theory, J. H. WATKINS (*Proc. Ga. Hort. Soc. 1893, pp. 62–66*).—This paper deals with experiments conducted to ascertain the effect of planting immature or prematurely ripened fruit seeds. Peaches were chiefly employed in the experiment. It was found that seeds planted from hastily ripened fruit possessed a low degree of vitality and a large percentage would not germinate. Such seedlings as grew produced fruit much earlier than did the parent tree, and in many cases of improved quality.

Field experiments with fertilizers on peach trees (*New Jersey Stas. Rpt. 1893, pp. 138–143*).—Notes on a continued experiment begun in 1884 on a private farm. Potash, either alone or in combination, has given the best results, while nitrate of soda appears to have exerted an unfavorable influence, except when used in connection with superphosphates.

Notes are also given for an experiment just commenced on another farm to test the effect of overfertilizing fruit trees, and the effect of nitrogen and phosphoric acid supplied in different ways, in one case by means of nitrate of soda and boneblack, and in another by ground bone and ground fish. In both cases potash is given as muriate of potash. On each of the fertilized plats the yield in 1893 was more than on an unfertilized plat.

Soil tests with fertilizers used on peach trees, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 13–16*).—Notes and tables showing the results of experiments conducted on 2 private farms to ascertain the value of the several soils and the fertilizers required by each. Both nitrogenous and potash fertilizers gave favorable results, but the best returns were found when the two styles of fertilizers were combined. Crimson clover is regarded as a valuable fertilizer. Mountain Rose, Crawford Early, and Foster were the varieties of peaches used in the test, which has been conducted 3 years and is to be continued.

Orchard fruits, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 364–373*).—Notes on the orchard work conducted at the California Foothill Station at Jackson, Amador County. This comprises comparative and cultural notes on the various varieties of apples, almonds, apricots, plums, prunes, cherries, nectarines, pears, and peaches. Several of the different kinds of fruits are planted on both red soil and granite soil to determine their relative value. Although in other places the granite soil is condemned, here it is found well adapted to many trees, responding rapidly to proper fertilizers. Tabulated data are given showing the dates of blooming and ripening of 62 varieties of peaches and the order of ripening of 17 leading varieties is compared with that of the same varieties in the valley of Alameda County. There is a well-marked difference, showing the preference in different varieties for different altitudes.

Orchard fruits at Paso Robles, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 380–392*).—Comparative and cultural notes on the orchard at the California Southern Coast Range Substation, data being given for 32 varieties of cherries, 13 of almonds, 49 of peaches, 9 of nectarines, 11 of apricots, 21 of plums and prunes, and several of apples, pears, olives, walnuts, chestnuts, quinces, mulberries, and figs. The work in the vineyard is mentioned, and notes given on 3 varieties of gooseberries and on the Logan berry.

Orchard fruits at San Joaquin Valley Station, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 404–410, pl. 1*).—Notes, chiefly cultural, on the orchard at this California substation, especially in regard to the methods of correcting the alkali soil, for which purpose gypsum has been found most valuable. Tabulated data are given for 10 varieties of apples, 18 of apricots, 3 of almonds, 10 of nectarines, 45 of peaches, 13 of pears, and 28 of plums and prunes. An engraving from a photograph is given showing the weakness of pear trees grown on strong alkali soil as compared with those on soil possessing less alkali.

Orchard fruits at the South California Substation, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 416–419*).—Brief notes on the orchard at this substation, which is making a fine growth, although so young that the yield is small. Notes are given on olives, lemons, oranges, almonds, cherries, peaches and nectarines, apricots, plums and prunes, pears, apples, figs, grapes, and walnuts and chestnuts.

The Logan berry, E. J. WICKSON (*California Sta. Rpt. 1893 and 1894, p. 340, pl. 1*).—Illustrated descriptive notes on this peculiar raspblackberry cross, which, in the station grounds, has proved to be a robust grower, with large handsome fruit, possessing a striking flavor suggestive of a combination of that of raspberries and blackberries. The plant appears to be free from all kinds of leaf diseases.

Notes on strawberries for 1894 (*New York State Sta. Bul. 76, pp. 429–444, pl. 1*).—Descriptive and cultural notes and tabulated data for 75 varieties of strawberries fruited on the station grounds for the first time. They were grown in matted rows on stiff clay loam, tile drained, and fertilized with barnyard manure. They were given one cultivation in the spring and mulched 4 or 5 in. deep with straw during the winter.

A table of productiveness showing also the season of ripening is given for 27 varieties, of which Allen No. 5 and Hayne No. 31 lead, with yields of 312 oz. and 283 oz., respectively, from 33 sq. ft. of ground. See No. 2 ranks third, with a yield of 196 oz. Of varieties ripening before June 21 and termed early, See No. 1 was the most productive. Of 10 late varieties, Station No. 198 gave the greatest yield after July 3. One hundred and sixty-four varieties of strawberries were grown at the station during the year, exclusive of several hundred varieties of station seedlings. The work at the station in breeding strawberries for the purpose of originating new varieties is mentioned.

Experiments with fertilizers on strawberries (*New Jersey Stas. Rpt. 1893, pp. 143–145*).—Notes on fertilizing 2 plats of strawberries with nitrate of soda, ground bone, and kainit. In addition 1 plat received nitrate of soda each spring. The latter plat gave an increase in yield of about 20 per cent.

The ash of grapes, F. T. BIOLETTI (*California Sta. Rpt. 1893 and 1894, pp. 322–326*).—Notes and tabulated data on the analyses of the ash of 5 samples of grapes and raisins and 1 of wine, to gain information as to the amount of soil ingredients taken from the ground and the fertilizers needed by the crop. The results are compared with those obtained from analyses in Europe and found to be much the same, the California analyses, however, showing a higher percentage of soda and a lower percentage of lime than was found by the European analyses. This is accounted for by the difference of soil, the California grapes being grown in rich interior valleys where the soil contained much potash and soda. As the phosphoric acid taken from the soil is proportionately large in amount, phosphatic manures are recommended, and the popular belief that the application of such manures to vineyards will communicate bad odors to wine is declared to be erroneous.

The following table shows the results of the analyses compared with those of wheat as regards the fertilizing ingredients taken up:

Ingredients abstracted from the soil.

	Total ash.	Potash.	Phosphoric acid.	Nitrogen.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*
5 tons of grapes per acre, average of 5 California analyses	50.00	25.48	10.62	12.60
5 tons of grapes per acre, average of 3 German analyses	50.00	25.07	10.50	17.00
Wheat hay (Johnson), 4,800 lbs per acre	246.00	43.92	19.80	42.00
Wheat (Johnson), 20 bu. per acre	24.00	7.85	11.90	24.00
Wine (Mataro, from Santa Clara County), 800 gal. per acre	15.37	6.67	2.30	.64

Cassava, J. H. HART (*Roy. Bot. Gard. Trinidad, Misc. Bul., 2 (1895), No. 1, pp. 25–27*).—Remarks on analyses of bitter and sweet cassava, showing that the nonpoisonous variety apparently does not exist in Trinidad. It is believed that the amount of prussic acid in sweet cassava is nearly equal to that in the bitter, and that too much confidence has been used in attributing non-poisonous properties to the sweet cassava. Careful boiling of sweet cassava in two or three waters is advised to expel all of the volatile prussic acid.

Castor beans, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 26, 27*).—Brief notes on crops grown in 1892 and 1893. An obscure blight caused the failure of this crop.

Echinocystis lobata, E. ANDRÉ (*Rev. Hort., 67 (1895), No. 1, pp. 9, 10, fig. 1*).—A description of this American curcubit, which is recommended as an ornamental plant chiefly on account of its oval-shaped spiny fruits.

Wild horse-radish, G. ALLUARD (*Rev. Hort., 67 (1895), No. 3, pp. 86, 87, fig. 1*).—Notes on its collection and preparing for market, with directions for cultivation.

The leeks, G. ALLUARD (*Rev. Hort., 67 (1895), No. 1, pp. 20–22, fig. 3*).—Descriptive and cultural notes on several varieties of leeks, giving directions for their best cultivation.

Onions from seed, C. L. NEWMAN (*Arkansas Sta. Rpt. 1894, pp. 93–95*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 419).

Salsify, C. L. NEWMAN (*Arkansas Sta. Rpt. 1894, pp. 95, 96*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 423).

Culture and cooking of Sechium edule (*Agl. Jour. Cape Colony, 7 (1894), No. 26, p. 614*).

Varieties of sweet potatoes, C. H. SHINN (*California Sta. Rpt. 1893 and 1894, pp. 420–424*).—Twenty-one varieties of potatoes tested at the Southern California Substation are described, and for a few of these the results of cooking tests are noted.

Best forms of food for the sweet potato crop, A. W. PEARSON (*Amer. Agr. (middle ed.), 1895, Mar. 23, p. 314*).—Advises use of chemical manures applied some months before planting.

The cultivation of tomatoes on a large scale in the vicinity of Paris, G. ALLUARD (*Rev. Hort., 67 (1895), No. 2, pp. 45–47, fig. 1*).—A general article on the subject dealing with the cultural method and describing some of the varieties most in use.

A new method of etiolation, E. A. CARRIÈRE (*Rev. Hort., 67 (1895), No. 1, pp. 12, 13, figs. 2*).—Description of a method of blanching chicory and other salad plants by placing a cask over the growing plant with its sides perforated with holes to allow free circulation of air. The method is claimed to be very successful.

Truck farming on the coast lands, G. M. RYALS (*Proc. Ga. Hort. Soc. 1892, pp. 26–29*).—Notes on market gardening in the coast region of Georgia, with remarks on the preparation and fertilizing of the land, the character of seed to be used, and shipping and marketing. Celery is regarded as an especially valuable crop.

Some apples adapted to all sections of Arkansas, J. T. STINSON (*Arkansas Sta. Rpt. 1894, pp. 44–47*).—A reprint from Bulletin 26 of the station (E. S. R., 5, p. 1075).

Arkansas seedling apples and nursery stock, J. T. STINSON (*Arkansas Sta. Rpt. 1894, pp. 48–50*).—A reprint from Bulletin 26 of the station (E. S. R., 5, p. 1075).

Analyses of figs, G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 225–235*).—A reprint from Bulletin 102 of the station (E. S. R., 5, p. 301).

Figs at the Foothill Station, G. HANSEN (*California Sta. Rpt. 1893 and 1894, pp. 375–378*).—Comparative notes on some of the varieties of figs grown at this California substation. Fifty-two varieties are planted. The variety Hirtu du Japon is considered the best bearer. Of the white varieties White Adriatic, DuRoi, and White Marseilles; of brown, Drap d'Or and Brown Turkey; and of black, Pasteliere and Rond Noir were most satisfactory.

Figs at Tulare Station, J. FORRER (*California Sta. Rpt. 1893 and 1894, pp. 411–414*).—Descriptive and comparative notes on 39 varieties of figs grown at this substation.

The mango, J. H. HART (*Roy. Bot. Gard. Trinidad, Misc. Bul., 2 (1895), No. 1, pp. 11–13*).—Cultural notes on *Mangifera indica*, especially in reference to the soil and grafting. It is stated that if well cultivated, mangoes will produce sweet, pleasantly flavored fruit that deserves a wide reputation. The varieties cultivated at the botanic gardens are named.

The mangosteen, J. H. HART (*Roy. Bot. Gard. Trinidad, Misc. Bul., 2 (1395,) No. 1, pp. 10, 11*).—Notes on the tree and fruit of *Garcinia mangosteena*, which has been introduced from the East Indies into Trinidad, where it is growing well, and the fruit being liked. The mangosteen possesses a thick, brittle, bitter rind, which readily cracks off, exposing the white pulp divided into quarters. Only 1 or 2 mature seeds are produced by each fruit.

Olive culture, A. P. HAYNE (*California Sta. Rpt. 1893 and 1894, pp. 298–322*).—Cultural notes for the olive, comprising remarks on pruning, curing, harvesting, and storing of the fruit and the expression of the oil. The greater part of the paper is a reprint from Bulletin 104 of the station (E. S. R., 6, p. 141).

Twig budding and grafting the olive, E. J. WICKSON (*California Sta. Rpt. 1893 and 1894, pp. 339, 340*).—A brief note on the subject, including a letter from an experienced orchardist, detailing methods employed by him in budding and grafting, which have proved most successful.

Olives and olive oil, A. P. HAYNE (*California Sta. Rpt. 1893 and 1894, pp. 279–297, pl. 1*).—Descriptive notes on the trees and fruit of 20 varieties of olives, with analyses showing the number of olives in 100 gm. and the percentage of pit, flesh, and oil in the fruit. Fifty-six varieties of olives are now planted at the various substations.

The peach palm, J. H. HART (*Roy. Bot. Gard. Trinidad, Misc. Bul., 2 (1895), No. 1, pp. 28, 29*).—Descriptive notes on *Guilielma speciosa*, which is found growing well in Trinidad. The palm usually bears two crops in a year, that in October being composed of large fruit with abortive seeds, while the other consists of small fruits with hard fertile seeds. The October fruit is boiled and eaten with salt, and is considered a very nutritious human food.

Japanese plums, L. H. BAILEY (*Rev. Hort., 67 (1895), No. 2, pp. 51, 52*).—Translated from *Gardener's Chronicle*, giving brief descriptive and comparative notes on the chief varieties of Japanese plums that have been introduced and grown in America.

Examination of California prunes, apricots, plums, and nectarines, G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 257–268*).—A reprint of Bulletin 101 of the station (E. S. R., 4, p. 918).

Analyses of prunes and apricots, G. E. COLBY (*California Sta. Rpt. 1893 and 1894, pp. 268–271*).—Descriptive notes on 6 varieties of prunes and 1 of apricot, with a table giving in detail the results of the proximate analyses. The sugar content in all the instances was below that determined by previous analyses. French prunes possessed the most sugar, 13.95 per cent.

Catalogue of the fruit trees at the California Experiment Stations (*California Sta. Rpt. 1893 and 1894, pp. 474–490*).—This comprises long lists of the varieties planted at the central station and at 4 substations, there being given 274 varieties of apples, 18 of crab apples, 23 of almonds, 48 of apricots, 40 of cherries, 5 of chestnuts, 2 of citron, 68 of figs, 6 of lemons, 10 of mulberries, 17 of nectarines, 20 of oranges, 169 of peaches, 166 of pears, 120 of plums and prunes, 7 of persimmons, 8 of quinces, and 19 of walnuts.

Fruit culture in north Georgia, J. C. MILLER (*Proc. Ga. Hort. Soc. 1892, pp. 68–70*).—General remarks on fruit growing in northern Georgia, the author believing that fruits can be produced here equal to those grown in California.

Catalogue of Georgia fruits (*Proc. Ga. Hort. Soc. 1892, pp. 71-86; 1893, pp. 69-85*).—An annotated list and tabulated data for various kinds of fruit successfully cultivated in Georgia, the State being divided into 4 sections, the upper or mountain, the middle, the southern, and lower or coast region.

Fruits of Bohemia, F. THOMAYER (*Rev. Hort., 67 (1895), No. 1, pp. 17, 18*).—Historical notes on several varieties of apples, peaches, and other fruits which have been originated in Bohemia, which has for centuries been noted for its orchards and its production of valuable varieties of fruits.

Fruit culture in Gironde, C. GÉRAND (*Rev. Hort., 67 (1895), No. 4, pp. 74-76*).—Short articles giving the status of fruit growing in this Department, with lists of the preferred varieties.

Various methods of soil improvements in orchards, N. Schneider (*Rev. Hort., 67 (1895), No. 1, pp. 22-25; No. 2, pp. 48-50*).—General remarks on the subject dealing with manuring and tilling the ground.

An implement for vine grafting, E. André (*Rev. Hort., 67 (1895), No. 4, pp. 67, 68, fig. 1*).—Illustrated description of an apparatus for cutting the stems of grape vines in making various kinds of grafts.

Notes on pruning deciduous fruits, W. H. Tyson (*California Sta. Rpt. 1893 and 1894, pp. 397-400*).—General remarks on the subject and special directions as to the proper pruning to be given almonds, apricots, prunes, apples, pears, cherries, and peaches. Severe pruning is advised for most cases, low, round heads to be established.

The effect of pruning and training on the natural habits of the grape, S. D. Riegel (*Proc. Ga. Hort. Soc. 1892, pp. 32–34*).—General notes on the subject, with a discussion of the respective value of various systems. Fuller's oblique training is recommended for trellises, and the serpentine system for stakes. Intelligent pruning is urged.

Earliness vs. quality in fruits, S. Hape (*Proc. Ga. Hort. Soc. 1892, pp. 67, 68*).—A short popular paper urging that early fruits are apt to be immature and possess little or insipid flavor.

Transportation of fruits and vegetables, W. L. Glessner (*Proc. Ga. Hort. Soc. 1893, pp. 26–28*).—A general discussion of the problem of the transportation of horticultural products, picking, packing, and shipping being in turn considered. Care in icing the refrigerator cars is urged.

Canning vegetables and fruits (*Amer. Agr. (middle ed.), 1895, Mar. 5, p. 252*).—Tabulated data give the results obtained at a California cannery regarding the number of pounds of each fruit and vegetable required to make 100 lbs. of canned goods, amount of sugar required, and cost of labor in canning.

Canning, drying, and preserving fruit, A. H. Benson (*Agl. Gaz. N. S. W., 5 (1894), No. 12, pp. 857–866*).

A new process of preparing raisins, A. Petit (*Rev. Hort., 67 (1895), No. 1, pp. 69, 70*).—A brief description of a scheme of curing raisins by exposing them to an atmosphere of alcohol vapor at 60° F. for 2 months.

Report of horticulturist (*Mississippi Sta. Rpt. 1893, pp. 33–37*).—A report on the horticultural work of the station, strawberries and grapes having received most attention, and being treated of at greatest length. Cultural notes are given for these fruits. The horizontal trellis is preferred for training grapevines. Cottonseed hulls are recommended as mulch and fertilizer for strawberries, and ashes for fertilizing grapes. Lists of the preferred varieties of strawberries and grapes are given.

FORESTRY.

The chestnut in the West, C. A. Keffer (*Garden and Forest, 8 (1895), p. 83*).

The honey locust in the West, C. A. Keffer (*Garden and Forest, 8 (1895), p. 112*).—The tree has flourished very well on the dry uplands of western Kansas, although a failure at the South Dakota Station.

Notes on the distribution of the yellow pine in Nebraska, C. E. Bessey (*Garden and Forest, 8 (1895), pp. 102, 103*).

Species of cork-forming trees, H. Mayr (*Centbl. Ges. Forstw. Wien, 21 (1895), No. 2, pp. 55-57*).—The author enumerates *Ulmus suberosa*, *Acer campestre*, *Euonymus europæus*, *Fraxinus anomala*, *Xanthoxylum clava-hercules*, *Quercus suber*, *Q. occidentalis*, etc.

The lesson of the forest fires, B. Hubbard (*Pop. Sci. Monthly, 1895, Mar., pp. 586–596*).

The forestry stations, C. H. Shinn (*California Sta. Rpt. 1893 and 1894, pp. 425–432*).—A brief history of the establishment and a report on the present condition of the forestry stations at Chico and Santa Monica are given.

SEEDS—WEEDS.

Distribution of seeds, plants, cuttings, etc., E. J. WICKSON (*California Sta. Rpt. 1893 and 1894, pp. 343–362, fig. 1*).—A report is given of the distribution by the station of seeds, plants, cuttings, etc., since 1890, the details of the offerings having appeared in Bulletins 95, 98, and 103 of the station (E. S. R., 3, p. 444; 4, p. 557; 5, p. 683). Statistics are given of the distributions since 1886, showing that there were sent out 52,310 plants and cuttings and 40,457 ounces of seed. Brief reports are given by the voluntary experimenters on the materials sent out. A list of donations to the station since December, 1892, is appended.

Some Oregon weeds, M. CRAIG (*Oregon Sta. Bul. 32, pp. 99–116, figs. 9*).—The author gives illustrated descriptive notes on 5 troublesome weeds, as follows: Canada thistle (*Cnicus arvensis*), bull thistle (*C. lanceolatus*), sow thistle (*Sonchus arvensis*), spiny or dagger cockle bur (*Xanthium spinosum*), and Russian thistle (*Salsola kali tragus*). The State laws relating to the destruction of Canada thistle and dagger cockle bur are given, and in addition to the ones enumerated above the author suggests that the laws be modified to include French pink (*Centaurea cyanus*), dog fennel (*Anthemis cotula*), tarweed (*Madia* spp.), white mustard (*Brassica campestris*), oxeye daisy (*Chrysanthemum leucanthemum*), and moth mullein (*Verbascum blattaria*).

Directions are given for the destruction of weeds in general, with specific directions for the 5 species particularly mentioned in the bulletin.

Germination of black walnuts and acorns, G. B. SUDWORTH (*Garden and Forest, 8 (1895), pp. 105, 106*).—The author accounts for the prolonged vitality of seeds deeply planted as due to the probably accidental but proper adjustment of moisture conditions.

The vitality of seed, A. PETER (*Nachrichten Kl. Ges. wissensch. Göttingen; abs. in Nature, 51 (1895), Feb. 28, p. 422*).—The author gives the results of a second series of cultural experiments with dormant seeds taken from various depths in the soil of woodlands or forest. "The forest in question was the site of villages and cultivation that disappeared several centuries ago; and some of the samples were taken from a dense forest, 100 to 150 years old, under the shade of which there has been no surface vegetation for years. The principal point to investigate was the probable existence of seeds of cornfield weeds still possessing the power of germinating and developing into reproductive plants. The author succeeded in raising a large number of plants belonging to about 50 species, including some of the weeds of cultivation; and he believes he has good grounds for supposing that many pasture plants and cornfield weeds retain their vitality for more than a half century, under the conditions he describes."

On the seeds of Moabi, H. LECOMTE and A. HÉBERT (*Compt. Rend., 120 (1895), No. 7, pp. 374–377*).

On the seeds of the Coula of the French Congo, H. LECOMTE and A. HÉBERT (*Compt. Rend., 120 (1895), No. 4, pp. 200–202*).

Methods of planting and destroying Bermuda grass, C. L. NEWMAN (*Arkansas Sta. Rept. 1894, pp. 103–108*).—A reprint from Bulletin 28 of the station (E. S. R., 6, p. 439).

A method of destroying dodder, A. SERVAIS (*Ingén. Agr. Gembloux, 5 (1895), No. 8, pp. 354, 355*).—The plants on the spots where dodder is present are carefully removed and burned, the spot is worked with a hoe or rake, and orchard grass or some other quick-growing species is planted on the infested spot. The author states that dodder thus treated may be entirely eradicated within 2 years.

Troublesome grasses of southern New Jersey, M. TREAT (*Garden and Forest, 8 (1895), pp. 103, 104*).—Notes are given on *Elusine indica, E. ægyptiaca,* Bermuda grass, and coco or nut grass.

DISEASES OF PLANTS.

Fungus diseases of plants, B. D. HALSTED (*New Jersey Stas. Rpt. 1893, pp. 326–436, figs. 63*).

Synopsis.—Notes are given on fungi on weeds, strawberry diseases, club root of cabbage and its allies, soil rot of sweet potatoes, on the identity of the anthracnose of watermelon and bean, fungus diseases of the muskmelon, some fungus diseases of the pea, a fatal disease to truck crops, field observations upon fruit decays, decays of mature apples, blight of ornamental spurge, fungus diseases of cultivated sedums, hollyhock fungus diseases, some carnation fungus diseases, mint rust on balm, fungus diseases of ornamental bulbous plants, anthracnose of rose, ivy blight, palm diseases, blights of dracæna, orchid diseases, blight of ornamental ferns, bacteria in some of their relations to crop growing, leaf blight of calceolaria, dropsical pelargoniums, and notes on a new *Exobasidium.*

Fungi on weeds (pp. 326, 327).—Notes are given on several fungi that serve to keep some of our worst weeds in check. The species of fungi mentioned are *Cystopus candidus* on the shepherd's purse and some other cruciferous plants, *C. portulacæ* on the common purslane, and *Puccinia suaveolens* on the Canada thistle. A report is given of the last-named fungus having nearly exterminated an acre of the thistle, scarcely a plant maturing any seed.

Diseases of the strawberry (pp. 327–332).—The more important fungus diseases of the strawberry as enumerated are: Leaf spot (*Sphærella fragariæ*), leaf blight (*Phyllosticta fragaricola*), leaf spot (*Septoria aciculosa*), leaf spot (*Ascochyta fragariæ*), anthracnose (*Glæosporium fragariæ*), leaf blight (*Ramularia modesta*), and mildew (*Peronospora fragariæ*). Of these the leaf spot (*Sphærella fragariæ*) is perhaps the most destructive. The author reviews the more important contributions on this disease since 1887, when there was given a comprehensive bibliography.[1] Another of the leaf spots (*Ascochyta fragariæ*) may easily be mistaken for this disease. A new strawberry leaf blight has been under investigation by the author since 1892. It was first discovered near Syracuse, New York, and it seems to be far from rare, though often obscured by the presence of other fungi. The disease is caused by a fungus apparently of the genus *Aposphæria.* This fungus appears to prefer the upper surface of the leaf, but develops its pycnidia on both sides of the leaf. The affected portions lose their characteristic green and soon become brown. The pycnidia first appear as minute elevations of the same color as the leaf, but as the spores mature they become amber colored and rise prominently from the leaf. Inoculations under a bell jar gave within 10 days well-developed pycnidia on healthy leaves. As a rule it is only the old leaves that are affected and these should be burned. Bordeaux mixture may prove effective against this blight.

---

[1] U. S. Dept. Agr. Rpt. 1887, p. 340.

Club root of cabbage and its allies (pp. 332–345).—This is a reprint of Bulletin 98 of the station (E. S. R., 5, p. 685).

Soil rot of sweet potatoes (pp. 345, 346).—A report is given of some field experiments conducted with the view of checking the soil rot of sweet potatoes. Series of rows of plants growing in infested soil were treated as follows:

"(1) On May 13, 2 rows while still open and before manuring, were sprayed thoroughly with the Bordeaux mixture.

"(2) On May 13, 2 rows sprayed as in 1 after the manure had been placed.

"(3) Two rows left untreated.

"(4) On May 13, 2 rows sprayed after they were made up and before setting the plants.

"(5) On May 20, 2 rows with the plants sprayed directly after setting.

"(6) On August 10, 2 rows sprayed after the plants had run vines 18 to 20 in. long."

The results obtained showed "that spraying the rows before the addition of manure is the better way of treating the ground for the prevention of the soil rot of the sweet potato." There appears, from the tabulated results given, a gradual increase in the amount of soil rot present from the first series to the last.

Identity of the anthracnose of the bean and watermelon (pp. 347–352).—The author reports having inoculated citrons on opposite sides of a line with spores from the bean and watermelon. Both inoculations grew rapidly and nô differences could be detected, proving the identity of the two diseases. The author reviews the synonymy of the fungus and concludes the name should be *Colletotrichum lagenarium*.

Fungus diseases of the muskmelon (pp. 352–356).—Mention is made of three of the more important diseases of the muskmelon. The first is a downy mildew (*Plasmopara cubensis*), similar to the downy mildew of the grape and amenable to the same treatment. The second is of a bacterial nature. Parts of the plant, as the stem, petioles, or leaf blades, when attacked have a peculiar watery appearance. The author thinks it probable that the germs of this disease may be carried over from year to year in the soil, and probably several crops may be affected by the same disease. Spraying is thought to check the disease. The third trouble is a leaf spot due to a species of *Phyllosticta*. It is confined to the leaves and younger parts of the vine, and it seems very probable that it could be controlled by spraying with any of the more common fungicides.

Some fungus diseases of the pea (pp. 357–362).—Several fungus enemies of the pea are described, the more important being pea mildew (*Erysiphe martii*), pea rust (*Uromyces appendiculatus*), pea blights (*Ascochyta pisi* and *Septoria pisi*), black mold of pea (*Pleospora pisi*), damping off (probably *Pythium debaryanum*), a bacterial disease, and a disease attacking the seed, producing dark olive patches on the seed coat a few days after planting. These diseases may occur singly or more commonly associated with some of the others. The nature of their attack on the host is described, and the use of fungicides and selection of sound seed recommended as preventive treatment.

A fatal disease to truck crops (pp. 362–366).—Specimens of diseased tomato, eggplant, and other plants were sent the author from the Florida Experiment Station, and the disease was recognized as similar to one on lupines in Louisiana, in which a *Penicillium* developed abundantly when placed in a moist chamber. Cultures made from the Florida material developed sclerotia abundantly in a short time. Cultures were made on the stems of corn, squash, cucumber, and several weeds, upon all of which the fungus grew vigorously. Open-air cultures were not so successful, and on some plants the fungus was made to grow only by exercising great care, and it is thought that while the disease may be very destructive in Florida it will not prove serious in the latitude of New Jersey. The study of this disease is still in progress.

A field observation upon fruit decays (pp. 366, 367).—In Bulletin 91 of the station (E. S. R., 4, p. 657) the author reported on a decay of quinces due to *Sphæropsis malorum* and claimed that the source of contamination was an apple tree near by. A visit was made in July, 1893, to the orchard, and while there was no decay manifest on the quinces and pears, a grafted branch of the suspected apple tree was loaded with fruit, a large per cent of which was decayed. The fruit on the remaining branches of the tree was unaffected. The obvious remedy in this case was removing the graft of the early variety of fruit (Red Astrachan).

Decays of mature apples (pp. 367–377).—This is a reprint of a popular article[1] in which are described specking of apples, apple scab, mold, blotch, bitter rot, and black rot.

Blight of ornamental spurge (pp. 377–379).—An anthracnose of euphorbias, due to *Glœosporium euphorbiæ*, is described.

Fungus diseases of cultivated sedums (pp. 379–381).—Two diseases of sedums are described, an anthracnose due to *Septoria sedii*, and a disease due to *Vermicularia telephii*. The affected portions should be collected and burned to prevent the spreading of the diseases.

Hollyhock diseases (pp. 381–383).—Descriptions are given of a hollyhock rust (*Puccinia malvacearum*), a leaf spot (*Cercospora althæina*), and a leaf blight (*Phyllosticta althæina*). All sorts of hollyhocks are subject to these diseases. The author recommends that seed should be saved only from plants free from disease, that all young plants known to be affected should be rejected, and that old plants be sprayed with Bordeaux mixture at least once a week during the growing season.

---

[1] Pop. Sci. Monthly, 1893, May.

Some fungus diseases of carnations (pp. 384–391).—A popular paper read before the American Carnation Society, January, 1893, describing carnation leaf spot (*Septoria dianthi*), anthracnose (*Volutella* sp.), leaf mold (*Heterosporium echinulatum*), and a bacterial disease. Remedies are suggested for carnation diseases, the most successful ones being sprays of potassium sulphid solution, Bordeaux mixture, and ammoniacal copper carbonate.

Mint rust on cultivated balm (pp. 391, 392).—The mint rust (*Puccinia menthæ*) is reported on the cultivated balm (*Melissa officinalis*). The form of rust present is the one having echinulate teleutospores and is known as form *americana*.

Fungus diseases of ornamental bulbous plants (pp. 392–396).—Diseases of lilies, hyacinths, tulips, narcissus, gladiolus, and crocus are described. The rejection of all diseased bulbs is advised as a precautionary measure.

Diseases of cyclamens (pp. 396–399).—Diseases due to *Phoma cyclamenæ*, *Botrytis vulgaris*, *Colletotrichum cyclamenæ*, and a bacterial disease are described.

Diseases of callas (pp. 399–401).—A bacterial disease, one due to *Phyllosticta richardiæ*, a disease due to *Cercospora richardiæcola*, and another due to *Pestalozzia richardiæ* are mentioned.

Rose anthracnose (pp. 401–405).—In the Annual Report of the station for 1892, p. 280 (E. S. R., 5, p. 399), mention was made of several destructive diseases of roses, among them an anthracnose due to *Glœosporium rosæ*, which causes the defoliation of the canes. Further investigations of this disease show that the whole plant is infested by the fungus, which saps its vitality to such a degree that those leaves showing no trace of disease are unable to perform their usual functions. The appearance and habit of growth of this fungus are similar to the raspberry anthracnose (*G. venetum*), and the author suggests their probable identity. Young plants or young shoots are most susceptible to the disease. Roses that have a sickly colored foliage, with the leaves falling prematurely, especially from the tips of the canes, may be suspected of being attacked by the anthracnose, and the pink blotches may be seen by the aid of a hand lens on the leaves and stems. All affected canes should be cut, and, together with the fallen leaves, gathered and burned. Sound plants may be protected by frequently spraying them with Bordeaux mixture or ammoniacal copper carbonate.

A blight of variegated ivy (pp. 405–407).—A blight of the variegated forms of the English ivy is reported due to *Vermicularia trichella*. All variegated plants are especially susceptible to fungus diseases, as the etiolated portions are less able to resist the entrance of the spores. All diseased leaves of such plants should be removed and the remaining ones protected by sprays of copper compounds.

Palm diseases (pp. 407–411).—Several diseases of palms, especially Kentias, are figured and described. All diseased leaves or parts of leaves, which may be recognized by the dead or discolored spots, should be removed and the remaining foliage sprayed at least once a week with Bordeaux mixture. A leaf blight of caryotas is also described and the same treatment recommended.

Blights of dracænas (pp. 412–414).—A blight, due to *Phyllosticta maculicola*, causing small brown angular spots in the leaves, surrounded by yellowish areas, is described. Another blight more destructive to the thick leaved dracænas is caused by *Vermicularia concentrica.* A third disease, a leaf tip blight of *Dracæna fragrans*, caused by *Glæosporium* sp., is illustrated and described. The author thinks these diseases could be prevented to a great degree by the use of any of the standard fungicides.

Orchid diseases (pp. 414–419).—Leaf diseases of *Sorbralia macrantha* and *Bletia volutella*, and petal blights are described. Care in not propagating from diseased plants and use of fungicides are advised as preventive treatment.

Tip blight of ornamental ferns (pp. 419–421).—Fern blights are described and Bordeaux mixture as a preventive treatment advised.

Bacteria in some of their relations to crop growing (pp. 422–430).—A reprint is given of a semipopular paper on bacteria read before the New Jersey Horticultural Society.

Bacterial leaf blight of calceolarias (pp. 430, 431).—A disease, due to *Micrococcus* sp., is described as causing brownish patches on the lower leaves.

Dropsical pelargoniums (pp. 432, 433).—Numerous instances are reported of pelargoniums being spotted, but no fungus could be found. The author thinks it probable that the plants were affected by the same cause, resulting in what has been called œdema of tomato.[1] The remedy recommended is a cooler, dry soil, with increased light wherever possible.

Notes on a new Exobasidium (pp. 434–436).—Notes are given on *Exobasidium peckii*, a fungus almost entirely confined to the inflorescence of *Andromeda mariana*, its attack resulting in abnormally developed flowers.

Report of the mycologist, F. D. CHESTER (*Delaware Sta. Rpt. 1893, pp. 103–131, figs. 2*).

Synopsis.—A report is given on the treatment of peach rot and blight; observations on root rot of crimson clover, diseased cowpeas, and anthracnose of tomato; and a report of bacteriological work in various lines, principally in the preparation of attenuated anthrax virus.

Treatment of plant diseases (pp. 103–109).—Experiments were conducted in 2 orchards for the prevention of peach rot and blight. The treatment consisted in (1) winter treatment, the removal of all mummy fruits and washing the trees with a copper sulphate solution; (2) spraying twice before the buds opened; (3) spraying with Paris green for curculio; and (4) spraying when the fruit began to show color to prevent attacks of the rot. In the first orchard the fungicides used as sprays were ammoniacal copper carbonate and suspended copper carbonate with glue. As a result of the winter treatment it was found that 26 per cent blighted blossoms were on the unsprayed trees, as compared with 12 per cent on those given treatment and 17 per cent on those given the early spraying but no winter treatment. Owing to the fruit not having been gathered according to directions, the results of the other treatments were lost.

---

[1] New York Cornell Sta. Bul. 53 (E. S. R., 5, p. 55).

In the second orchard the same treatments were tested with 3 additional fungicides, viz, copper and ammonium carbonate, copper acetate, and copper sulphate and calcium chlorid solutions. The results obtained indicate encouraging benefits from spraying, and the question of whether winter treatment and early spraying is not sufficient is to be the subject of further experiment. The use of Paris green was attended with a greater total yield over their checks, amounting to about 3 times the yield where no treatment was given. There was a decreased amount of rot present in those trees having been treated for that disease.

Observations on plant diseases (pp. 109–115).—The author made cultures of the crimson clover root rot, *Sclerotinia trifoliorum*, previously published as *S. trifolium*,[1] and found it would grow readily on indifferent media. This shows its power to live as a saprophyte as well as parasitically on its host. Any cultivation that tends to stir the soil will tend to eradicate the fungus.

A lot of cowpea seed was sown, and the developing plants were so badly diseased as to require a replanting. The second lot of seed was examined and 9.5 per cent found to be affected by *Colletotrichum lindemuthianum*. The presence of the disease can be recognized by the spotted appearance of the seed, and all such should be rejected.

Notes are given on the ripe rot or anthracnose of tomato. In the Annual Report of the station for 1891, p. 60 (E. S. R., 5, p. 59), this disease was described as due to *C. lycopersici*, n. sp., but the author has since decided it as identical with *C. phomoides*, the name by which the fungus should be known. The author made numerous inoculations with the spores, and found that they would as readily grow on the pepper, grape, and apple as on the tomato, a fact which he thinks points toward the probable identity of the ripe rots of these fruits.

Bacteriological work (pp. 115-131).—The author gives in detail the methods followed in preparing an attenuated anthrax virus for use in the protection of cows against anthrax. The method employed was that of attenuation by heat, keeping the cultures at a temperature of 42 to 43° C. for a time, the different lots being tested until the required attenuation is secured. Examinations were made by the author of milk and a supposed case of anthrax in man without finding the specific bacilli present, while they were found in a case of anthrax in a horse.

---

[1] Delaware Sta. Rpt. 1890, p. 84 (E. S. R., 3, p. 689).

A microscopical examination of 4 lots of wheat bran was made to ascertain the presence of cockle-seed meal. In none of the samples was there any important admixture. The presence of cockle may be readily recognized when at all abundant by the characteristic saponin bodies.

The author made a study of some of the mold fungi to test the common belief that cerebro-spinal meningitis is due in some way to these fungi. Jars of bread paste were exposed in a stable where several horses had died with the above disease. The species of molds collected were: *Aspergillus nigricans*, *A. fumigatus*, *Rhizopus nigricans*, and *Penicillium glaucum*. The only fungus of interest was the *Aspergillus fumigatus*, and from this cultures were made on oats. Nothing positive is shown as to the ability of these molds to produce the disease in question. However, a rabbit inoculated with 0.5 cc. water containing spores of *A. fumigatus* died in 5 days. Cultures made from the viscera of the rabbit did not develop any of the mold in either agar tubes, Petrie plates, or bread-paste jars.

The southern tomato blight (*Mississippi Sta. Rpt. 1893, pp. 53–61, fig. 1*).—A report is given of 3 years' experiments, conducted by F. S. Earle at the Ocean Springs substation, for the prevention of the tomato blight, reported in Bulletin 19 of the station (E. S. R., 3, p. 702). The experiments consisted in soil treatments in the field and bed and spraying the plants with well-known fungicides. Based on 1 year's experience, the author thinks that whether the blights of tomatoes, potatoes, and watermelons are identical or not they are not easily communicated from one crop to another under the ordinary field conditions.

The author presents the following tentative conclusions:

"(1) In preparing compost for the seed bed and cold frame, use a liberal amount of lime, kainit, ashes, or other potash salt. This will give good, stiff-stemmed, stocky plants, which are better able to resist blight.

"(2) A few days before sowing the seed sprinkle the bed thoroughly with strong Bordeaux mixture and rake it in.

"(3) After the plants are set in the field add Paris green to the Bordeaux mixture and continue to spray at intervals of 10 days or 2 weeks until the fruit is half grown. Care must be exercised in spraying after the fruit is set, as it is more easily injured than is the foliage.

"(4) Never plant tomatoes on land where they grew the previous year, and at least 2 years' rest is much safer.

"(5) While this station does not recommend the practice of following either melons or potatoes with tomatoes, it records the fact that it can often be done with safety."

A new disease of the olive tree, A. P. HAYNE (*California Sta. Rpt. 1893 and 1894, pp. 297, 298*).—The author reports the presence in various parts of the State of a new leaf disease of olives, which he has determined as probably due to *Cycloconium oleaginum*, a fungus which is rather common in southern Europe. He quotes G. Boyer, of the École Nationale d'Agriculture, Montpellier, France, who has made an exhaustive study of the disease. Both surfaces of the leaf are attacked, but more commonly the upper, where it forms circular spots, black, gray, or brownish in color, the center usually being of a different color from the surrounding portions of the spots. The spots vary from 6 to 15 mm. or more in diameter and are irregularly distributed over the leaf, and may sometimes be found on the peduncle and fruit. The fungus may appear any time of the year, but its most serious attack is usually late in the summer or autumn. The black color is due to the presence of the abundant dark-colored spores, and as these become scattered the color becomes lighter.

In California the only variety on which the disease has been observed is the Mission. Its attack is so insignificant that at least for the present no treatment is required.

Experiments in winter spraying of apples and pears, C. W. WOODWORTH (*California Sta. Rpt. 1893 and 1894, pp. 441–462*).—Notes and extensive tables on experiments in spraying apple and pear trees for two seasons against the oyster-shell scale, greedy scale, and woolly aphis, conducted in the station orchard at Berkeley. A plat is given showing the arrangement of the trees treated. Various insecticides and fungicides were used, both alone and in combination. The results, as indicated by the elaborate detail of the several tables, seem to show but little value from the treatment. Formulas are given for the preparation of various insecticides and fungicides and the indications for their use are mentioned.

Peach yellows experiments, M. H. BECKWITH (*Delaware Sta. Rpt. 1893, pp. 152, 153*).—The author reports experiments with seedling peach trees and with trees brought from a region where the yellows is not known, in which it is shown that such trees are no more capable of resisting the disease than others.

A disease of mulberries, A. PRUNET (*Compt. Rend., 120 (1895), No. 4, pp. 222–225*).—The author claims that there is great confusion in the diseases of the mulberry, due to their varying manifestations. He thinks there is a disease of the mulberry similar to that of the grape, which he has called chytridiose, and that it is due to a species of *Cladochytrium*, to which he has given the name *C. mori*. It differs from *C. viticolum*[1] in its smaller zoösporangia, cystes, and zoöspores. Its attack on the mulberry is very similar to that of the related species on the grape. The treatment recommended is the same in each case, applications of solutions of iron sulphate.

The black rot and its practical treatment, G. LAVERGNE and E. MARRE (*Le Black rot et son traitement pratique. Bordeaux: Féré, 1895*).—The authors have prepared a condensed manual based on their observations made in 1894 during an official examination of the black rot and its practical treatment.

Their conclusions are as follows:

---

[1] Compt. Rend., 119 (1894), No. 19, pp. 808–811 (E. S. R., 6, p. 642).

"(1) After the grapes are gathered, collect all dried grapes and those which have fallen from the bunches, together with all the leaves that are strewn on the ground, and burn them.

"(2) Prune as closely as possible, eliminating all the young sprouts. Collect and burn the cuttings.

"(3) During the latter part of March wash the vines with an acid solution of copper sulphate to which there may be added iron sulphate if anthracnose be suspected, the formula recommended being copper sulphate 10 kg., iron sulphate 10 kg., sulphuric acid 1 kg., hot water 100 liters.

"(4) Upon the return of spring and when the young shoots are 6 to 10 cm. in length apply Bordeaux mixture, using 3 kg. copper sulphate to 3 kg. of lime. Apply whenever the atmospheric conditions will allow and repeat if washed off by rain.

"(5) Ten or 15 days later, depending on the size of the sprouts, give a second spraying.

"(6) Give a third, fourth, and if necessary a fifth spraying at intervals of 15 to 30 days, dependent on the atmospheric conditions.

"(7) Before the time for the appearance of oïdium, dust the vines with sulphur and dry copper sulphate or with copper sulphosteatite.

"(8) Supplement these treatments if practicable by collecting and burning the first leaves attacked by the black rot.

"(9) Wherever there has been no previous severe attack, the first 3 suggestions may be omitted, but by following out all the directions the vineyard will be free not only of black rot but of mildew as well."

A new treatment for grape mildew, L. SIPIÈRE (*Compt. Rend., 120 (1895), No. 4, pp. 220–222*).—The author reports the successful use of lysol as a remedy against grape mildew. He was led to make a trial of this material (1) on account of its well-known power as a germicide, (2) its ready solubility in water, (3) its harmlessness, and (4) its cheapness. It was used in solutions varying in strength from 0.001 to 0.01, the best results being obtained when used in the strength of 0.005, which is obtained by adding 5 gm. of lysol to every liter of water. When used in the strength recommended it proved as efficacious as Bordeaux mixture and was more economicalby 28 per cent. Three sprayings are necessary, and in France the proper time for their application is April 20 to 30, May 1 to 8, and June 1 to 8. When used in a strength of 0.004 it rids the leaves of all insects or larvæ that may be on them, and it may be used to rid the vine of all kinds of parasites.

The author thinks lysol will prove equally as effective against oïdium as it is shown to be against the mildew.

A laboratory of plant diseases, C. W. WOODWORTH (*California Sta. Rpt. 1893 and 1894, pp. 435, 436*).—A description is given of the laboratory of the University of California for the especial study of plant diseases.

Apple canker (*Gard. Chron., 17 (1895), ser. 3, p. 242*).—A controversial article in which the author thinks conditions of planting and natural hardiness have more to do with the disease than fungus attacks.

The canker of larch (*Oesterr. forst. Ztg., 13 (1895), No. 2, pp. 11, 12*).—A popular article on the diseased condition due to *Peziza wilkommii.*

Concerning Nectria ditissima, F. BANDISCH (*Centbl. Ges. Forstw. Wien, 21 (1895), No. 2, pp. 51–55*).—A popular article on the cause of canker in trees.

Root knots of fruit trees and vines, C. W. WOODWORTH (*California Sta. Rpt. 1893 and 1894, pp. 436–440, pl. 1*).—This article is a revised and enlarged reprint from Bulletin 99 of the station (E. S. R., 4, p. 563).

Hexenbesens (*Oesterr. forst. Ztg., 13 (1895), No. 2, p. 12*).—A description of witches broom of a 90-year-old pine tree.

A vine disease of Chile, A. GIRARD (*Rev. Vit., 2d ser., 3 (1895), No. 64, pp. 233–236*).—It is attributed to *Margarodes vitium.*

The relationship of Cæoma nitens and Puccinia peckiana, G. P. CLINTON (*Bot. Gaz., 20 (1895), No. 3, pp. 116, 117*).—Notes are given on the identity of the two forms and a discussion of the proper nomenclature for the fungus.

New species of Ustilagineæ and Uredineæ, J. B. ELLIS and B. M. EVERHART (*Torrey Bul., 22 (1895), No. 2, pp. 57–61*).—Technical descriptions are given of 14 new species, divided as follows: *Ustilago,* 1; *Entyloma,* 1; *Uromyces,* 2; *Puccinia,* 9; and *Æcidium,* 1.

Plant diseases caused by cryptogamic parasites, K. FREIHERR v. TUBEUF (*Pflanzenkrankheiten, durch kryptogame Parasiten verursacht. Berlin: J. Springer, 1895, pp. 600, figs. 306*).

How to distinguish fungus diseases of carnations, B. D. HALSTED (*Florists' Exchange, 7 (1895), No. 14, pp. 293, 294*).—Paper read by the author before the American Carnation Society. Carnation rust, leaf spot, black spot, ring mold, and bacteriosis are described. Copper sulphate 1 to 1,000 solution has given good results against these diseases and does not have the lime which is often objectionable in Bordeaux mixture.

Effect of treating barley seed for smut, M. HOLLRUNG (*Fühling's landw. Ztg., 44 (1895), No. 2, pp. 49–53*).

Experiments in treating potato blight, A. SEMPOTOWSKI (*Deut. landw. Presse, 22 (1895), No. 6, p. 51*).—A brief report on the use of Bordeaux mixture and sulphate of iron and lime.

Spraying of apple trees, J. T. STINSON (*Arkansas Sta. Rpt. 1894, pp. 23–44, fig. 1*).—A reprint from Bulletin 26 of the station (E. S. R., 5, p. 1076), giving details of experiments conducted for the prevention of apple scab and bitter rot.

Lysol as a fungicide for vines, L. MANGIN (*Jour. Agr. Prat., 59 (1895), No. 7, pp. 245, 246*).

The preparation of ammoniacal copper carbonate solution, C. L. PENNY (*Delaware Sta. Rpt. 1893, pp. 172–183, figs. 2*).—A reprint from Bulletin 22 of the station (E. S. R., 5, p. 1077).

ENTOMOLOGY.

The San José scale in New Jersey (*New Jersey Stas. Bul. 106, pp. 24, figs. 5*).—This bulletin treats of the introduction and spread of *Aspidiotus perniciosus* in New Jersey, its life history, description, enemies, and treatment. The scale was introduced on Kelsey plum trees from California in 1886 or 1887 by two nurseries, and spread rapidly, attacking other fruits as well, especially pears. In 1889 or 1890 the first scaly stock was distributed from these nurseries to different parts of New Jersey and other States. In New Jersey the scale has not been found on the red shale soil which occupies the northern half of the State, although south of this it has been found in every county. As California fruit, pears in particular, are frequently infested by the scale, it is urged that great care be taken to avoid a further infection with the pest.

The scale is described in detail in the various stages of growth, and the life history given, the information being chiefly compiled.[1]

It was found that many deciduous fruit trees were attacked by the scale, though not all to the same extent. Currants, gooseberries, rosebushes, elms, and English walnuts were also found infested. Apples, pears, plums, and cherries are attacked in preference. Idaho and Louisiana pear trees suffer most, while Keiffer is least likely to be attacked.

The scale was found parasitized by the hymenopter *Aphelinus fuscipennis*, which attacks about 1 per cent of the scales. In addition, 2 species of ladybirds, *Chilocorus bivulnerus* and *Pentilia misella*, feed upon *Aspidiotus*.

It is recommended that every orchard that has been set out within the last 6 years should be thoroughly examined, and if the scales are found they should be brushed off, so far as possible, with a stiff brush. Following this the trees should be liberally pruned and the cuttings burned. The trees should then be washed or sprayed with whale-oil soapsuds, or with the following potash solution: Crystal potash lye, 1 lb.; fish oil, 3 pt.; soft water, 2 gal. To this water should be added to bring the amount up to 15 gal. The application of this insecticide should be made during a mild spell in the winter, and a month later the trees should be sprayed with strong kerosene emulsion. Spraying with diluted kerosene emulsion in the spring when the larvæ are crawling about is also recommended. The importance of carefully inspecting all nursery stock is insisted upon.

Some insects injurious to squash, melon, and cucumber vines, and the asparagus beetle (*New York State Sta. Bul. 75, pp. 409–427, figs. 3, pls. 4*).—This bulletin contains illustrated descriptive, life history, and remedial notes on the squash bug (*Anasa tristis*), squash-vine borer (*Mellitia ceto*), boreal ladybird (*Epilachne borealis*), melon louse (*Aphis cucumeris*), striped cucumber beetle (*Diabrotica vittata*), and asparagus beetle (*Crioceris asparagi*). The investigations were undertaken on Long Island and vicinity, where the insects seemed to be inflicting most damage.

The squash bug was unusually injurious the past season, and experiments were made with carbon bisulphid, pyrethrum powder, and kerosene emulsion for its destruction. Pyrethrum was found to be of no avail and the other insecticides of but little use. Cleaning the fields of rubbish and plowing in the fall is recommended, and in addition distributing bits of boards, chips, leaves, and the like underneath the vines, where the bugs will gather during the day and may be easily captured and killed. Picking the adult bugs from the vines in the early spring is also advised.

The squash-vine borer inflicted more damage than any other of the insects noted. Cutting out the borers as soon as the vines begin to show signs of injury and covering the bases of the vines with earth as far as the third or fourth joint is suggested, and also capturing and killing the moths which may be found sluggishly sitting on the leaves in the evening and early morning. Spraying with arsenites is recommended for the boreal ladybird. Kerosene emulsion or whale-oil soapsuds is advised against the melon louse, and picking and destroying the affected leaves. Against the striped cucumber beetle it is suggested that the hills be protected by covering them with screens or nettings of some kind until the vines have acquired a strong growth, and spraying with the arsenites, or dusting on tobacco dust, air-slacked lime, or a mixture of arsenites and plaster after the beetles have begun their attacks.

---

[1] U. S. Dept. Agr., Div. of Ent. Circular 3 (E. S. R., 5, p. 1088).

Against the asparagus beetle applying lime to the affected beds is recommended, and also cutting and burning the old stalks each fall and the young seedlings in the spring. It is also suggested that chickens be allowed to run among the beds.

Report on a so-called disease affecting the orange orchards of Wide Bay, and on insect pests prevalent therein (*Queensland Dept. Agr. Bul. 4, 2d ser., pp. 17*).—This deals with investigations on an affection of oranges called the "Maori orange," in which the fruit was covered to a greater or less extent with a brown stain, frequently obscuring the natural hue of the entire surface. The oranges were usually exceptionally sweet and juicy, but sometimes were black, and in this event the flesh was soft, discolored, and sour. The condition was found to be produced by the mite *Phytoptus oleivorus*, which fed upon the rind of the orange, puncturing the oil cells, from which the oil exuded and was oxidized by the atmosphere, thus producing a resinous dark stain. Treatment by means of a sulphur, soap, and water wash, or a spray of 2 oz. of potassium sulphid dissolved in 2 gal. of soapsuds is recommended. This insecticide should be applied in the spring before the growth commences, again when the fruit is the size of a marble, and later when it is about two thirds grown.

Descriptive, life history, and remedial notes are given on the white scale (*Chionaspis citri*), red scale (*Aspidiotus coccineus*), black scale (*A. ficus*), long mussel scale (*Mytilaspis gloveri*), and 5 species of brown scale (*Lecanidæ*). More persistent effort by fruit growers against injurious insects is urged.

Report of the entomologist, M. H. BECKWITH (*Delaware Sta. Rpt. 1893, pp. 154–171, figs. 7*).—This comprises a reprint of Bulletin 21 of the station (E. S. R., 5, p. 410) and some additional matter. A report is made of experiments with arsenites on several private farms to prevent the depredations of the curculio, the trees being sprayed with London purple, and the resulting fruit being almost entirely free from insect injuries. In another private orchard an experiment was conducted on 180 Abundance plum trees to determine the relative value of jarring and of spraying the trees to protect the fruit from the curculio. One half of the trees were jarred, this treatment being given 15 times, beginning on May 15 and continuing for 3 weeks. The other half of the orchard was given 3 sprayings with a mixture of Paris green and lime in water. Three times as much foliage and fruit dropped from the sprayed trees as from those that were jarred, but the opinion is held that spraying with arsenites is the most economical method of treatment. Two apricot trees were sprayed 3 times with Paris green to protect against the curculio, with beneficial results, although the fruit was severely injured by a fungus which attacked it when nearly ripe.

Descriptive, life history, and remedial notes are given on the elm-leaf beetle (*Galeruca xanthomelæna*), strawberry weevil (*Anthonomus signatus*), wheat-head army worm (*Leucania albilinea*), and strawberry-root aphis (*Aphis forbesi*), which proved destructive in the State. The strawberry-root aphis was especially prevalent and injurious in the neighborhood of Felton, but yielded to treatment with bisulphid of carbon, though the remedy is too expensive to be generally recommended.

Report of the entomologist, J. B. SMITH (*New Jersey Stas. Rpt. 1893, pp. 439–603, figs. 197*).

Synopsis.—This report contains a general review of the work accomplished during the year, brief remarks on special insect outbreaks, and more extensive notes upon the pear midge, pear-tree psylla, wheat-head army worm, strawberry weevil, corn-root webworms, pale-striped flea beetle, and chestnut weevils. The bulk of the report is taken up by a more or less popular paper on the chief beneficial insects.

General review (pp. 439–453).—Notes on the routine work of the office, with special remarks on several injurious insects, particularly the sweet-potato flea beetle, melon louse, onion maggot, wheat-head army worm, pale-striped flea beetle, strawberry weevil, pear midge, a new asparagus beetle, and some cranberry insects. The entomological inquiries and information that were published through the summer in the crop bulletins are quoted.

Pear midge (pp. 453–460).—Notes on the life history and devastations of *Diplosis pyrivora*, and experiments with treatment for it, which have been given in previous publications of the station.

Pear-tree psylla (pp. 460–465).—General life-history notes for *Psylla pyricola*. Scraping off the rough bark of the infested trees and washing the trunks and larger branches with a solution of whale-oil soap in the winter, and in the spring spraying the trees with kerosene emulsion is recommended.

Wheat-head army worm (pp. 465–469).—Notes on the unexpected appearance of *Leucania albilinea*, its life history, and remedies. The larvæ appeared early in July, causing considerable damage to ripening wheat. Later in the season the insects vanished, and are supposed to have returned to their normal food plants, the wild grasses. Plowing infested fields to a depth of 6 in. in the fall and again early in the spring is advised for the destruction of the pupæ.

Strawberry weevil (pp. 470–473.)—Descriptive and life-history notes for *Anthonomus signatus.* Covering strawberry beds by means of newspapers or screens of linen or cloth until the plants are in full bloom is advised, with a view to protecting the flowers until fertilization is accomplished.

Corn-root webworm (pp. 473–478).—Descriptive and life-history notes on *Crambus vulvivagellus*, with accounts of injuries and suggestions for treatment. Fall plowing, with a top dressing of kainit in the spring is advised.

Pale-striped flea beetle (pp. 478–480).—Brief notes on *Systena blanda* and damage inflicted by it. Underspraying with Paris green or London purple and lime as soon as the beetles are noticed is advised, adjacent weeds being also sprayed.

Chestnut weevils (pp. 481–485).—Life history and remedial notes on *Balaninus proboscoideus* and *B. rectus.* Planting of such varieties of chestnut trees as are least attacked, and the destroying of infested nuts as soon as they drop, are recommended.

Beneficial insects (pp. 485–603).—This part of the report comprises general popular remarks on the benefit derived by the farmer from predaceous and parasitic insects, and descriptions of many of the more important species are given in greater or less detail.

Entomology, F. L. WASHBURN (*Oregon Sta. Bul. 33, pp. 16, figs. 2, pls. 2*).

Synopsis.—This bulletin gives descriptive, life-history, and remedial notes on tent caterpillars, the grain plant louse, pear-leaf blister, and clover mite, with directions for making and using Koebele's resin wash.

Tent caterpillars (pp. 1–5).—The larvæ of 3 species of tent caterpillars (*Clisiocampa erosa, C. pluvialis*, and *C. constricta*) are described and remedies advised. The forms were abundant in the Willamette Valley during the season, the two first named species feeding upon various orchard trees, while *C. constricta* confined its devastations to oaks, particularly *Quercus garryana.* *C. pluvialis* was much less common than the two other species. The life history is briefly described and popular descriptions of the larvæ of each species are given. Brewer's blackbirds were found to eat the pupæ, but the hairy caterpillars were little molested by birds. Tachina and chalcid parasites were found to attack the larvæ, and some fungus diseases were also destructive, chiefly to *C. constricta.* Spraying with the arsenites is advised, but more particularly it is urged that the egg masses be gathered from the twigs of the fruit trees in autumn and winter and burned. An illustration on the cover of the bulletin is engraved from a photograph of the larvæ of the 3 species.

The grain plant louse (pp. 6–9).—*Siphonophora avenæ* was quite abundant in the wheat-growing districts, attacking also oats, rye, and mesquite grass. Its history and description are given. Burning stubble, weeds, etc., immediately after harvest, and then cultivating the land and allowing no grass or grain crop in the field the following year, is advised. It is recommended that badly infested wheat and oats be cut while green and used for hay. A lady beetle (*Hippodamia convergens*), syrphus flies, and several hymenopterous parasites were found to reduce greatly the numbers of the lice. An illustration from a micro-photograph is given showing an *Aphidius* parasite in the act of emerging from a dead grain aphis.

The pear-leaf blister (pp. 9–12).—Brief notes on the appearance and life history of *Phytoptus pyri* and the injury caused by it to the foliage of fruit trees. It has been found to be quite common in Oregon, and illustrations are given showing the damage done to leaves and an enlarged figure of the insect. Pruning and burning the infested branches and spraying with kerosene emulsion in the autumn when the mites are migrating are recommended.

The clover mite (pp. 12, 13).—Notes on *Bryobia pratensis*, which is found to be quite prevalent in Oregon, where it infests several kinds of fruit trees in addition to clover and grasses. It is recommended that infested fruit trees be sprayed with kerosene emulsion to which a little sulphur has been added.

Koebele's resin wash (pp. 13–15).—Notes on the preparing of a resin wash, 4 lbs. of resin, 3 lbs. of carbonate of soda, and 1 gal. of water being boiled together until the resin is dissolved, and then 4 gal. of warm water added. One part of this wash to 6 parts of water is recommended for the woolly aphis, and 1 part to 10 or 12 parts of water for other plant lice and the mealy bug. Experiments were made on plum trees infested with hop lice by spraying them with different strengths of the wash. One part of the wash to 15 parts of water destroyed the lice, but did not injure the larvæ of the syrphus flies or lady beetles that were preying upon the lice, and this strength is then recommended for use against these aphides.

Synopsis of the Dipterous genus Phora, D. W. COQUILLETT (*Canadian Ent., 27 (1895), No. 4, pp. 103–107*).

Preliminary studies in Siphonoptera, II, C. F. BAKER (*Canadian Ent., 27 (1895), No. 3, pp. 63–67*).—This part of the paper treats of the family *Pulicidæ*.

The biology of the Lachninæ in the valley of the Vistula, A. MORDWILKS (*Zool. Anz., 18 (1895), No. 46, pp. 74–85*).

Oviposition in Cicada hieroglyphica, J. B. SMITH (*Ent. News, 6 (1895), No. 3, pp. 84, 85*).—Brief note on this species depositing its eggs in the soft rotten wood of a cedar tree.

Successful introduction of humble-bees into New South Wales, A. S. OLIFF (*Ent. Monthly Mag., 2d ser., 6 (1895), No. 63, p. 67*).—An abstract from a letter on the subject.

What insects deserve the protection of foresters, farmers, and gardeners? L. TASCHENBERG (*Welche Thiere aus der Insectenwelt sind dem Schütze der Forstleute, Landwirte, und Gärtner sowie der allgemeinen Berücksichtigung zu empfehlen und warum? Friedländer & S., 1895, pp. 33. Reviewed in Wien. Ent. Ztg., 14 (1895), p. 47*).

A lac insect from Madagascar, A. TARGIONI-TOZETTI (*Bul. Soc. Ent. Ital., 26 (1895), No. 3 and 4, pp. 425–469*).—*Gascardia madagascarensis* is described as a new genus and species, and compared with other lac insects from India.

The bee-eating habit of Phymata erosa, W. METCALFE (*Biol. Rev. Ont., 1 (1893), No. 4, pp. 107–109*).—This insect is considered very injurious to bees, and lists are given of insects eaten by it and by *Reduvius raptatorius*.

Grain insects. R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Rpt. 1894, pp. 126, 127*).—A reprint from Bulletin 29 of the station (E. S. R., 6, p. 538).

The normal habitat of Pediculoides tritici, R. MONIEZ (*Rev. Biol. Nord. France, 7 (1895), No. 4, pp. 148–152*).—Notes on this insect, which is usually found in the stems of cereals, although sometimes it is parasitic upon man.

The potato stalk borer, Trichobasis trinotata, J. B. SMITH (*Ent. News, 6 (1895), No. 4, pp. 120–122, figs. 3*).—Notes on its devastation in New Jersey.

Notes on the cacao beetle, A. B. CARR (*Trinidad Field Nat. Club, 4 (1894), No. 4, pp. 110–112*).—Notes on the habits and devastations of *Steirostoma depressum*.

A new Chilean vine-destroying insect, E. C. REED (*Ent. News, 6 (1895), No. 3, pp. 85, 86*).—An account of *Margarodes trilobitum*, which is described as new.

Italian scale insects affecting the orange, A. BERLESE (*Le Cocciniglie Italiane viventi sugli agrumi, pt. 11, Avellino, 1894, pp. 201, pls. 13; extracted from Riv. Pat. Veg., 3 (1894), Nos. 1–8*).—This part of this elaborate work deals with the genus *Lecanium*.

Spread of Otiorhynchus ovatus, H. F. WICKHAM (*Soc. Ent., 1894, Dec., reprinted in Amer. Nat., 29 (1895), No. 338, pp. 177–179*).

Note on the invasion of locusts of the genera Ephippiger and Barbitistes, J. AZAM (*Bul. Soc. Ent. France, 1895, Feb. 27, pp. XLVII–L*).—The wingless species *Ephippiger terrestris* and *Barbitistes berengueri*, hitherto considered as rare and predaceous, do considerable damage to crops in France.

The gypsy moth in Massachusetts, W. C. WRIGHT (*Garden and Forest, 8 (1895), No. 368, p. 108*).—Urging that owners of comparatively small tracts of land can easily keep the insect in check.

An exterminator for the parasol ant, J. H. HART (*Roy. Bot. Gard. Trinidad, Bul. Misc. Inform., 2 (1895), No. 1, pp. 3–5, fig. 1*).—Illustrated description of a machine for smoking out the nest of this injurious ant, *Œcodoma cephalotes*.

Petroleum against the pourridie and the white grub, L. RAVAZ (*Rev. Vit., 2d ser., 3 (1895), No. 64, pp. 250, 251*).—Account of experiments, with good results in both cases.

Kerosene emulsion, S. B. CARPENTER (*Proc. Ga. Hort. Soc. 1892, pp. 34, 35*).—A popular paper on this insecticide, giving formulas for making it and directions for its application. It is advised that fruit trees that have been weakened by insect attacks be fertilized with sulphates in addition to being sprayed with kerosene emulsion.

Enemies to plant life and remedies, G. SPETH (*Proc. Ga. Hort. Soc. 1892, pp. 64–67*).—General remarks on various injurious insects and plant diseases, with recommendations for spraying with various chemical substances.

Entomological work at the Mississippi Station (*Mississippi Sta. Rpt. 1893, pp. 46, 47*).—A brief report on the nature of the entomological work carried on at the station during the year, giving a short account of the scope and aim of the experiments and investigations, and the bulletins issued.

FOODS—ANIMAL PRODUCTION.

Investigation of food materials, M. E. JAFFA (*California Sta. Rpt. 1893 and 1894, pp. 214–217.*)—This includes analyses of alfalfa hay, wheat, flour, bran, and screenings. The average analyses of these materials produced in California are compared with the averages of Eastern analyses. The alfalfa hay agreed quite closely with the average analysis of the same grown in the East. A comparison of wheat and its products is given as follows:

Average composition of wheat grown in California and the East, and products from the same.

	Number of analyses.	Moisture.	Ash.	Crude protein.	Crude fiber.	Nitrogen-free extract.	Crude fat.	Fuel value per pound.
Whole wheat:		*Per ct.*	*Per ct.*	*Per cent.*	*Per ct.*	*Per cent.*	*Per cent.*	*Calories.*
California grown, average	5	11.35	1.74	11.31	2.60	71.09	2.08	1,399
Eastern grown, average	310	10.05	1.80	11.90	1.80	71.90	2.10	1,419
Fine wheat flour:								
California, average	3	13.81	.47	7.90	....	76.40	1.39	1,627
Eastern, average	22	12.50	.50	11.00	....	74.90	1.10	1,645
Coarse wheat flour (graham):								
California	1	12.12	1.58	8.50	....	75.84	1.96	1,650
Eastern, average	3	13.10	1.80	11.70	....	71.70	1.70	1,625
Wheat bran:								
California, average	4	12.42	5.61	13.44	8.52	56.41	3.74	1,151
Eastern, average	88	11.90	5.80	15.40	9.00	53.90	4.00	1,152
Wheat screenings:								
California, average	2	11.16	2.94	10.06	5.48	67.63	2.72	1,123
Eastern, average	10	11.62	2.91	12.48	4.93	65.11	2.95	1,114

"From an inspection of the data given for California wheat, it will be seen that there is but little variation from the average obtained from 310 analyses of the same food material grown east of the Rocky Mountains. . . .

"The California flour is much poorer in nitrogenous compounds than the Eastern flour of the same quality.

"The same statement applies to graham flour.

"While the percentage of [phosphoric] acid in the ash of the different flours is about the same, amounting to almost one half the ash, when we refer it to the flour as 100, the coarse material shows 0.75 as against 0.23 for the fine flour. This is owing to the total ash in the former case being about three times that obtained for the latter. It must not be supposed that because the coarse or graham flour contains higher percentages of nitrogenous and mineral matter than does the fine flour it is therefore in proportion more nutritious. The increased amounts of these elements come from the bran, very little of which is digested by the human stomach."

"It will be noted that the bran made in California contains considerably less crude protein, or nitrogenous matter, than does the same by-product from the East, as shown in the averages, by the figures 13.44 and 15.40, respectively. The fat percentage is also slightly lower for the California food. . . .

"The wheat screenings of this State, like the bran, contain less of albuminoids."

Gluten feeds, their source, composition, and methods of use, E. B. VOORHEES (*New Jersey Stas. Bul. 105, pp. 24, fig. 1*).—By way of introduction an enlarged cut is given of a corn kernel showing the position of the skin or husk, gluten layer, starch layer, and germ. The skin, germ and starchy parts were separated from 100 gm. of kernels of new corn as nearly as possible, and analyzed with the following results:

Analyses of whole and separate parts of corn kernel.

	Amount secured from 100 parts of original corn.	Water.	Composition of the water-free material.							
			Crude fat.	Crude fiber.	Crude protein.	Crude ash.	Carbohydrates.	Nitrogen.	Phosphoric acid.	Potash.
	P. ct.	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*
Original corn	100.00	24.74	4.34	2.02	12.65	1.73	79.26	2.02	0.83	0.47
Skin	5.56	15.29	1.59	16.45	6.60	1.27	75.36	1.06	.23	.88
Germ	10.17	29.62	29.62	2.88	21.71	11.13	4 .79	3.48	6.16	2.91
Starchy and hard part	84.27	21.66	1.54	.65	12.23	.68	85.58	1.96	.35	.17

> "The germ, although only about 10 per cent of the whole kernel, contains 65 per cent of the fat, 61½ per cent of the mineral matter, 71 per cent of the phosphoric acid, 60 per cent of the potash, and 16½ per cent of the nitrogen, or protein. The remaining portions are characterized, the skin by its content of fiber, 51 per cent of the whole, and the starchy part by its carbohydrates, of which it contains nearly 90 per cent of that in the whole grain."

A brief explanation is given of the process by which the starch is separated commercially and the various by-products obtained:

> "The residue in this manufacture may consist either of one product, a mixture of the gluten, germ, and hulls, or of three, when the gluten, germ, and hulls are each separated. . . . The entire residue is in color brighter yellow than corn meal, and of a much more bulky character, owing to the presence of a larger proportion of bran; the trade name of this product is gluten feed. The gluten is distinguished by a higher content of both protein and fat, and a bright yellow color, and is called gluten meal. The germ is more bulky than the meals, shows a high content of crude fat, and is called germ meal or germ food. The hulls are very bulky, show a high content of crude fiber, and are usually sold as corn bran."

Samples of these various by-products from corn were obtained from dealers in the State and directly from manufacturers, and analyses of these are given in the bulletin. These are classified as follows: (1) Gluten feed, (2) gluten meal, (3) grano gluten feed, (4) corn oil meal and cake, and (5) corn germ meal and corn bran. The trade names of the materials analyzed were as follows: Chicago gluten feed, Peoria gluten feed, Buffalo gluten feed, dry gluten feed, Chicago maize feed, cream gluten meal, King gluten meal, Iowa golden gluten meal, gluten meal (flour), Hammond gluten meal, Chicago gluten meal, grano gluten feed, corn oil meal, corn oil cake, corn germ food, germ meal, corn bran, corn hulls, and analyses are also given of hominy chop and cerealine feed.

These materials as classified in the bulletin, with the possible exception of grano gluten feed, show very wide variations in composition. For instance, the gluten meals on an average contained somewhat more fat and about one half more protein than the gluten feeds, but the Chicago gluten meal "contains less than half as much fat and about 60 per cent more protein than the gluten feeds." The Chicago maize feed, which is classed with the gluten feeds, contains about one third less fat[1] than the other gluten feeds. The corn germ food contains three and a half times as much fat as the product from another factory sold under the name of germ meal, and the corn hulls have only one half as much fat as the corn bran. These variations in composition and the confusion in regard to names leads the author to suggest that—

> "Unless some good reason exists from the manufacturers' standpoint for the separation of the various parts of the corn, general use would be promoted by making but one product, which should consist of the total residue. It would relieve the purchasers of the uncertainty as to composition, reduce the danger liable to result

---

[1] The oil is said to have been partially extracted from this material.—ED.

from the careless feeding of the more highly concentrated parts of the residue, and abolish the necessity of a study of comparative values as now manufactured."

Statements are made in regard to the palatability and feeding value of these different feeding stuffs and suggestions regarding their use in compounding rations.

The determination of the ash, phosphoric acid, and potash in the whole kernel and in the various by-products is given as follows:

Ash constituents in corn and its by-products.

	Ash.	Phosphoric acid	Potash.
	Per cent.	*Per cent.*	*Per cent.*
Corn	1.50	0.70	0.40
Buffalo gluten feed	.87	.34	.08
Gluten meal	1.29	.56	.07
Chicago gluten meal	.89	.35	.06
Corn oil meal	2.28	1.36	.14
Corn bran	.81	.24	.06

"With one exception the original corn contains more total ash, and more phosphoric acid, and in every case more potash than any of the products derived from it as feeds."

In conclusion remarks are made on the value of the fertilizing ingredients of different feeding stuffs, and a table is given showing the pounds of fertilizing ingredients in a ton of a number of different cereals and by-products.

Feeding experiments with horses (*New Jersey Stas. Rpt. 1893, pp. 179–187*).—This is a continuation of the experiments in feeding horses reported in Bulletin 92 of the station (E. S. R., 4, p. 742). Two teams of horses on the college farm were divided into 2 lots, 1 horse from each team being in each lot. Both lots received alike 8 lbs. of timothy hay and 6 lbs. of corn. In addition lot 1 received 6 lbs. of dried brewers' grains, while lot 2 received 5 lbs. of wheat bran and 1½ lbs. of new-process linseed meal per head daily. The grain for each lot was mixed and fed in 3 portions, morning, noon, and night. The corn was at first fed whole, but afterwards ground. The experiment lasted 6 months, from June 1 to December 1, and was preceded by a preliminary trial of 1 week. All of the animals performed similar work. The horses were weighed each week, and a record is given of the changes in weight, food eaten, and general condition.

"The weights of the animals remained remarkably uniform. The difference between highest and lowest did not exceed 75 lbs. in any case, the lowest recorded occurring in July, except for horse No. 3, whose final weight was the lowest. The average weight for the 6 months is practically identical in all cases with the average weight of the first month, though it is lower in all cases than the first weight recorded, and is uniform for both lots.

"The uniformity in the amount of the food consumed and in the weight of the animals, in connection with the work performed, indicates no material difference in the usefulness of the two rations used. Both were entirely satisfactory."

The cost of the rations is based on the following prices: Timothy hay, $18; wheat bran, $17.50; corn meal, $22; dried brewers' grains,

$17; and linseed meal, $29 per ton. At these prices the cost of the brewers' grain ration was 19.8 cts. per day for horse 1, and 18.9 cts. for horse 3; and the wheat-bran ration, 20.8 and 22.3 cts., respectively.

"It is observed that the cost of the daily rations used is much less than is ordinarily charged for feeding work horses. . . .

"That is, for the 6 hardest-working months of the year a farm horse of 1,000 lbs. live weight may be fed for $30.84, when dried brewers' grains furnish the bulk of the necessary protein, and for $33.49 when wheat bran and linseed meal are the chief sources of this nutrient; on the basis of actual cost of the rations only, the brewers'-grains ration is slightly more satisfactory, or 8.6 per cent cheaper than the wheat-bran ration. When the fertility value of the dried grains, wheat bran, and linseed meal is regarded as of importance, the differences in the rations are less marked."

Mention is made of a market gardener in the State who reports saving about 20 per cent on the cost of keeping horses by feeding a ration similar to that given to lot 1. Assuming that the cost of feeding the horses and mules of the State is 20 per cent higher than it need be, which is believed to be a conservative estimate, "the expense of feeding the horses of the State for the 6 working months would be reduced by $700,000 if more rational measures were adopted."

Fodders and feeds (*New Jersey Stas. Rpt. 1893, pp. 158–178*).—Analyses are given of green crimson clover, cowpea vines, corn stalks, corn fodder, shelled corn, sugar beets, corn cob, corn meal, gluten meal, gluten feed, brewers' grains, wheat bran, cotton-seed meal, linseed meal, rice polish, and Paine's stock feed; the market prices of a large number of commercial feeding stuffs from 1891 to 1894; an article on corn stalks and straw as hay substitutes, reprinted from Bulletin 96 of the station (E. S. R., 5, p. 499); and the average composition of a large number of feeding stuffs, largely compiled.

The relative values of winter and spring wheat bran, A. T. NEALE and C. L. PENNY (*Delaware Sta. Rpt. 1893, pp. 16–18, 191*).—Analyses of 4 samples of wheat bran from spring, winter, and local wheat, with a statement of the weight per double bushel, the selling price, and the calculated value according to the station's basis of valuation. In the latter respect the local product was below the others. The heavier bran was valued the highest.

Feeding stuffs, C. L. PENNY (*Delaware Sta. Rpt. 1893, pp. 191, 192*).—Analyses of crimson clover straw, crimson clover chaff, crimson clover seed, peavines (green), gluten feed, distillery corn feed, and wheat bran.

An easy method for detecting a common adulterant of ground pepper D. MARTELLI (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 53–56*).

Fruit as an article of diet and as a medicinal agent, J. P. H. BROWN (*Proc. Ga. Hort. Soc. 1892, pp. 35–37*).—General and popular remarks on the healthfulness of a fruit diet, different fruits and vegetables being recommended for various minor disorders of the system.

The feeding of farm animals, E. W. ALLEN (*U. S. Dept. Agr., Farmer's Bul. 22, pp. 32*).—This is a popular bulletin on the principles of feeding; feeding standards; maximum, minimum, and average composition of the principal feeding stuffs; calculation of the digestible materials in a large number of common feeding stuffs; calculation of rations for cows, steers, pigs, etc.; the origin of by-products used as feeding stuffs; preparation of food; and wheat as a food for animals.

Stock feeding, G. L. TELLER (*Arkansas Sta. Rpt. 1894, pp. 137–170*).—A reprint of Bulletin 30 of the station (E. S. R., 6, p. 663).

Further notes on the use of peanut oil as a substitute for milk fat in calf feeding, M. PETERSEN (*Braunschw. landw. Ztg., 63 (1895), No. 3, p. 10*).

Feeding for milk (*Mississippi Sta. Rpt. 1893, pp. 30–32*).—Short accounts of work previously published in Bulletins 13 and 15 and reprinted in the Annual Reports of the station for 1890 and 1891 (E. S. R., 2, pp. 362, 658; 3, pp. 166, 875).

Salting cows (*Mississippi Sta. Rpt. 1893, p. 32*).—A reprint from the Annual Report of the station for 1888 (E. S. Bul. 2, pt. 1, p. 108).

Milking (*Mississippi Sta. Rpt. 1893, pp. 32, 33*).—A reprint from the Annual Report of the station for 1888 (E. S. Bul. 2, pt. 1, p. 108).

The preparation of food for swine, WERNER (*Braunschw. landw. Ztg., 63 (1895), No. 4, pp. 14, 15*).—Grinding and steaming grain, the preparation of potatoes and Jerusalem artichokes and roots, the effect of different foods on character of flesh and lard, and the amounts of different foods required to produce 1 kg. of increase in live weight are briefly discussed.

VETERINARY SCIENCE AND PRACTICE.

Cerebro spinal meningitis in horses, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 23–39*).—The subjects treated are the prevalence, symptoms, *post-mortem* appearances, theories as to the causes, and experimental studies on the causes of this disease.

The following food stuffs were suspected of having caused the disease: Good corn silage, decayed corn silage, musty-blade fodder, musty-top fodder, musty oats, and wheat bran. All of these foods were fed to animals believed to be susceptible, but with negative results. German veterinarians believe that wheat cockle (*Agrostemma githago*) under certain conditions that are not well understood causes death in horses. Hens fed largely on ground cockle died, their symptoms being those of narcotic poisoning. But another flock of fowls ate perfectly dry cockle seed without visible injury; grain screenings containing a large proportion of cockle were fed to a colt with negative results. The results were also negative when screenings were first fermented and afterwards dried and ground.

To determine whether stinking smut of wheat (*Tilletia lævis*) had any connection with meningitis, wheat bran infested with this fungus was fed to a horse with negative results. The feeding of oats containing *Aspergillus fumigatus* also gave negative results.

Hydrophobia in farm stock, A. T. NEALE and P. GIBIER (*Delaware Sta. Rpt. 1893, pp. 48–59, fig. 1*).—Two outbreaks of hydrophobia in Delaware are noted. A general discussion of hydrophobia and an abstract of the German laws on the subject are given, as well as brief notes on a horse and dog successfully treated with vaccine after being bitten.

"A temperature of 70° C. (158° F.) will destroy the microbe [of hydrophobia] after a few minutes' exposure; desiccation destroys it in a few hours . . . and acids and disinfectants destroy it easily; but it resists putrefaction for a time and keeps its virulent properties for several weeks when it is kept cold. . . . The virus of hydrophobia can be put with impunity in contact with the skin or taken through the mouth without causing any disturbance. . . . The almost unique way of propagating the disease is by a bite. . . . It is not necessary to submit the stables or yards in which cattle affected with rabies have been confined to the same disinfection which would be required for anthrax or glanders. Washing with hot water containing a small quantity of sulphuric acid, followed by spontaneous desiccation, will be sufficient. . . . Cauterization, even when applied a few moments after the bite with the strongest acids, caustic, or cautery, is not sufficient to protect against the infection. . . . I would rather suggest that the wound be washed with a [1 per cent] solution of bichlorid of mercury, peroxid of hydrogen, or any strong disinfectant."

Investigations concerning bovine tuberculosis, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 7, pp. 178, pls. 6*).—This bulletin consists of articles on the following subjects:

Clinical and pathological notes on a herd of 60 cattle treated with tuberculin, F. L. Kilbourne, E. C. Schroeder, and T. Smith (pp. 7–74).—In a herd of 60 animals tested with tuberculin this method of diagnosis acted correctly, indicating the presence or absence of tuberculosis in 86⅔ per cent of the cases. Of 53 tuberculous animals, 47 were affected with tuberculosis of the organs situated in the chest. "Infection by way of the intestinal tracts was indicated in 14 cases by tuberculosis of a smaller or larger number of mesenteric glands."

Further experimental observations on the presence of tubercle bacilli in the milk of cows, E. C. Schroeder (pp. 75–87).—Of 19 specimens of milk obtained from the general milk supply of Washington one sample contained the bacillus of tuberculosis in sufficient numbers to produce the disease in 1 of the 2 guinea pigs injected with it.

Studies in bovine tuberculosis with special reference to prevention, T. Smith (pp. 88–128).—The author finds that the extent and rapidity of the disease of the lungs depends at least in part upon the number of tubercle bacilli inhaled either within short or long periods of time, and that tuberculosis of the lungs is not necessarily associated with any other recognizable lung affection as a preëxisting favoring condition.

Some practical suggestions for the suppression and prevention of tuberculosis, T. Smith (pp. 129–146).—The danger of infection from different sources is summarized by the author as follows:

"(1) Fully nine tenths of all diseased animals have been infected by inhaling the tubercle bacilli, dried and suspended in the air.

"(2) Fully one half of all diseased animals have been infected by taking tubercle bacilli into the body with the food. Frequently both food and air infection are recognizable in the same animal.

"(3) Animals are infected, though rarely, during copulation. In such cases the disease starts in the uterus and its lymph glands or in the sexual organs and corresponding lymph glands of the bull.

"(4) Perhaps from 1 to 2 per cent of all calves are born tuberculous."

The presence of tuberculosis in one herd is not believed to endanger other herds near by which do not mingle with the diseased herd in pasture or stable. In the absence of the tuberculin test the stockman is advised to remove from his herd and have destroyed—

"(1) All animals which show emaciation with coughing and any suspicious discharges from the nose.

"(2) Those animals with enlarged prominent glands about the head (in front of the eyes, under and behind the lower jaw), all enlarged glands in front of the shoulder, in the flanks and behind the udder.

"(3) Animals with suspected tuberculosis of uterus and udder."

Tuberculin and its use, A. E. de Schweinitz (pp. 159–178).—"The danger of injecting tuberculin into healthy animals in moderate quantity is slight. In healthy guinea pigs I have found that an injection of a dose 20 times as large as that required to produce a reaction in a diseased cow may kill, but does not always do so."

Examinations were made of samples of cow's milk (1) the day before injection, (2) the day after injection when the temperature was about at the maximum, and (3) a day or two after injection.

"In general the results show a decrease in total solids in the [milk of] tuberculous animals after the injection. In the healthy animals there is also a slight decrease in solids, but not as much as in the diseased animals.

"There is also a decided variation in the proportion of fat before and after injection of the tuberculin as well as albuminoids and sugar. The fat and sugar decrease, the albuminoids show a slight increase. The latter may, in part, be attributed to the presence of a small amount of tuberculin in the milk. This variation in the constituents of the milk would indicate that while under examination with tuberculin the milk of the animals should either not be used at all, or close attention paid to the fact that tuberculin will cause such variations. These results are but preliminary to a more extended examination."

Bovine tuberculosis, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 81–102*).—The condition of public sentiment and the prevalence of bovine tuberculosis in the State are discussed at length. Ten herds, comprising 344 cows, were examined by the station veterinarian. Of these 89 animals were condemned. A rise of 1.5° in the temperature of an animal was sufficient for condemnation. The average expense for tuberculin exceeded 50 cts. per head. "About 1 cow in every 10 thus far killed and examined by this station for tuberculosis had a consumptive udder."

The method of disinfection followed by the station was to spray the stables with a 1 per cent solution of chlorid of lime in a spraying pump worked under a pressure of more than 100 lbs. to the square inch. A small quantity of whitewash was added to the solution in order to mark the thoroughness of the work. This solution "when driven through the air by heavy pressure charges the barn so heavily with chlorin gas that laborers are sorely tried while carrying out the work. A barn thus sprayed and closed for a few hours must be regarded as sterilized as thoroughly as circumstances will allow." Tabulated data give the temperature records of the animals tested with tuberculin.

Anthrax, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 60–81*).—This general discussion of anthrax is largely a reprint of Bulletin 20 of the station (E. S. R., 5, p. 413). The use of Pasteur's preventive vaccine for anthrax is discussed, and experiments in which the use of vaccine failed to give immunity against the disease are briefly described. The Delaware law relative to the reduction of infectious and contagious diseases among the lower animals is given.

Ringworm (Trichophyton tonsurans) in cattle, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 59, 60*).—An outbreak of ringworm, followed in several instances by death, is noted. "Mercurial ointments, spirits of camphor, salicylic acid, and especially tincture of iodin are recommended for local application."

Texas or splenic fever, A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 39–47*).—A reprint of Bulletin 23 of the station (E. S. R., 6, p. 81).

The use of Koch's lymph in the diagnosis of tuberculosis in cattle, J. NELSON (*New Jersey Stas. Rpt. 1893, pp. 209–285, dgms. 5*).—This article was printed as Bulletin 101 of the station (E. S. R., 6, p. 332).

Diseases of stock, R. R. DINWIDDIE (*Arkansas Sta. Rpt. 1894, pp. 1–22*).—A reprint of Bulletin 25 of the station (E. S. R., 5, p. 995).

Diseases of man and of domestic animals spread by dogs, O. HENNING (*Agl. Jour. Cape Colony, 8 (1895), No. 2, pp. 55, 56*).

Veterinary work of the Mississippi Station (*Mississippi Sta. Rpt. 1893, pp. 43–46*).—Reference is made to publications of the station treating of anthrax or charbon, diseases of sheep and calves, dehorning, glanders, and colic. Preventive treatment and symptoms of anthrax are discussed, and prescriptions to be used in the treatment of cramp colic and wind colic are given.

DAIRYING.

Fluctuation in the volatile acids of butter fat, C. L. PENNY (*Delaware Sta. Rpt. 1893, pp. 183–191*).—In this study the volatile fatty acids were determined in samples of butter from a large creamery taken at frequent intervals from September 16, 1891, to December 22, 1893. During the first year the samples were kept some time, often a year or more, before the volatile acids were determined. After that the samples were saponified, usually on the same day the butter was made. In all 118 samples were tested, and the results are tabulated, with the averages by months. The changes by months are also illustrated by a diagram.

"Inspection of the table shows that the results vary greatly and very suddenly within the same month, frequently much more than the averages of successive months; and the same month in 2 successive years shows wide differences probably due to more permanent causes. There would seem to be no relation between season and percentage composition of butter fat that is not overbalanced and entirely hidden by other disturbing causes. But following the changes from month to month it will appear that there is great uniformity of tendency. At certain times in the year the percentage of volatile acids, whatever it may happen to be for the year and under the particular circumstances, falls off rapidly, at other times it increases slowly and again rapidly. The falling off in percentage of volatile acids appears to be relatively abrupt. At a particular time of the year we can not say with any approximation to certainty what the proportion of volatile acids will be, but we may say with some confidence that at a certain season it will be increasing, at another decreasing. From July to September in the year 1892 this proportion is quite different from what it is during the same months of 1893, yet the rate of increase is substantially the same and also the same as that found by Spallanzani.[1] From September there is a rapid decline, continuing in our experience till October or November, in [Spallanzani's] to December. There is then an almost continuous rise till June, when there is an instant falling off to July. The two maximum points are September and June, the two minimum points from October to December, or late autumn, and July. The fact that the results for the same month of different years vary so rather emphasizes these tendencies. Then if the quality of butter improves with a higher percentage of volatile acids, the best butter ought to be made in June and in September, the poorest in July and in the late autumn. The minimum percentage in the above table is 21.77 on October 3, 1891, the maximum 32.23 on May 4, 1893. . . . The results are believed to show as fairly as may be the effect of season alone on the composition of butter-fat. The extreme fluctuations here reported are naturally less wide than might be found between samples from different individual cows."

---

[1] Staz. Sper. Agr. Ital., 32 (1889), March.

A scheme for paying for cream by the Babcock test in butter factories, J. M. BARTLETT (*Maine Sta. Bul. 15, 2d ser., pp. 4, pl. 1*).—In this bulletin a popular detailed description is given of the method of carrying out the payment for cream at creameries on the basis of its weight and fat content, instead of its volume alone. The cream is to be weighed by the collector and a small sample taken by means of a sampling tube, and placed in a 2-oz. bottle marked with the patron's number. Upon arrival at the creamery the small sample bottles are emptied into the composite sample jars of the respective patrons, and these composite samples preserved by means of bichromate of potash for 2 weeks (4 weeks in winter), when they are tested by the Babcock tester. The method of paying for the cream from the results of the test is illustrated.

In the sale of milk, which offers the more profitable market, the creamery or a milk association of Philadelphia? A. T. NEALE (*Delaware Sta. Rpt. 1893, pp. 19–21*).—The financial record is given by months of two dairymen, one of whom sent his milk to Philadelphia and the other to a creamery which paid by test. The first sent 33,214 qts. of milk to Philadelphia during the year, receiving $1,027.23 net or 3.1 cts. per quart. The milk averaged 4.3 per cent of fat for the year. The second sent 33,214 qts. of 5 per cent milk to the creamery, receiving $1,076.84. Had the first sent his 4.3 per cent milk to the creamery he would have lost $101.04, and had the second sent his 5 per cent milk to the city he would have lost $49.63. "That is, in the city trade, no distinction in price is made between a product with 5 per cent and one with 4.3 per cent of butter. Yet on 33,214 qts. of milk, this difference on the creamery basis amounted to $150.67."

Test of hand separator, C. L. PENNY (*Delaware Sta. Rpt. 1893, p. 192*).—The power required to run a DeLaval Baby Separator at the rate of 41 turns per minute was found to be 0.1 horsepower. Run at 47 turns per minute the skim milk contained 0.1 per cent of fat.

The preparation of a new drink from milk, A. BERNSTEIN (*Deut. landw. Presse, 22* (*1895*), *No. 14, pp. 119, 120*).

Inoculation in the manufacture of koumis, P. SPALLANZANI (*Staz. Sper. Agr. Ital., 28* (*1895*), *No. 1, pp. 43–52*).

Flaack's milk sterilizer (*Deut. landw. Presse, 22* (*1895*), *No. 7, pp. 56, 57*).

The Patterson method for determining the amount of butter-fat in milk (*Mississippi Sta. Rpt. 1893, pp. 48–50*).—An account of a modification of the Beimling method, previously described in Bulletin 21 of the station (E. S. R., 4, p. 267).

AGRICULTURAL ENGINEERING.

Tile drains, S. M. TRACY (*Mississippi Sta. Rpt. 1893, pp. 37–40*).—Accounts are given of attemps at the station during 1889–'93 to tile drain "creek bottom lands underlaid by a very heavy, almost impervious, black soil and clay; black prairie soils; and 'seepy' clay hillsides." The effect of the tiles was evident not only in removal of excess of water but in mitigation of drought on soils subject to it.

"When the drains have been less than 500 ft. in length we have found 3-in. tile ample for draining the ground quickly and thoroughly, but for longer runs we have found it necessary to use 4-in. for the lower part of the drains, and this has been of sufficient size for the extremities of the longest runs, about a quarter of a mile. The tile have been put into the ground to an average depth of 3½ ft. and the expense of the work, including the cost of tile, digging the ditches, laying and covering the tile has been 51 cts. per running rod. Three-inch tile have cost, including freight, about $18 per thousand feet, which is nearly three times the cost of such tile in Illinois and other Northern States. . . .

"The station fields which have been tile drained have increased their annual yield fully 50 per cent as a result of the work, and such drains will be found a profitable investment on all soils which remain wet until late in the spring on account of their compact subsoil, or which are rendered heavy and 'sour' by continued seepage from surrounding hill lands."

The artesian wells of southern Wyoming, their history and relation to irrigation, J. D. CONLEY (*Wyoming Sta. Bul. 20, pp. 87–122, figs. 2*).—The conditions necessary for an artesian supply are explained; the extent of artesian irrigation in San Bernardino, California, and the San Luis Valley, Colorado, is noted; and a detailed account of the artesian wells of southern Wyoming, principally in the vicinity of Laramie and Rawlins, is given, including data relating to cost, flow, strata pierced, and analyses of the water.

In an appendix is given the official analyses of water from artesian wells sunk by the Union Pacific Railway Company in Wyoming.

Brush and stone drains (*Cult. and Country Gent., 1895, Feb. 7, p. 103, figs. 2*).—Popular directions for the construction of these drains.

Subirrigation (*Rural New Yorker, 1895, Feb. 2, p. 66*).—A system of subirrigation by means of tile drains is described, which is claimed to overcome most of the objections to irrigation by means of tiles.

Petroleum motor in agriculture, BRUTSCHKE (*Wochenschr. Pom. ökon. Ges., 25 (1895), No. 2, pp. 14, 15*).

Results of trials of potato diggers, F. SCHOTTE (*Jahrb. deut. landw. Ges., 9 (1894), pp. 395–410, figs. 15*).

Machines for peeling potatoes, F. SCHOTTE (*Jahrb. deut. landw. Ges., 9 (1894), pp. 389–394, figs. 4*).

Plans for a piggery, MALOCHOWSKI (*Jahrb. deut. landw. Ges., 9 (1894), pp. 411–416, figs. 3*).

STATISTICS.

Reports of director and of treasurer of Arkansas Station (*Arkansas Sta. Rpt. 1894, pp. V–VIII, 84, 85*).—A brief review of the year, a financial statement for the fiscal year ending June 30, 1894, and a list of the bulletins published by the station since July, 1891.

Arkansas Southern Branch Station, R. L. BENNETT (*Arkansas Sta. Rpt. 1894, pp. 87–89*).—Brief general remarks on the work at this substation.

Financial statements for 1893 and 1894 (*California Sta. Rpt. 1893 and 1894, pp. 495, 496*).—Financial statements for the fiscal years ending June 30, 1893 and 1894.

Report of treasurer of Delaware Station (*Delaware Sta. Rpt. 1893, pp. 4, 5*).—This is for the fiscal year ending June 30, 1893.

Reports of director and of treasurer of the Mississippi Station for 1893 (*Mississippi Sta. Rpt. 1893, pp. 1–6, 46, 52*).—Report of the treasurer for the fiscal year ending June 30, 1893, and brief outlines of the work of the year in the different departments at the station and at the branch stations at Holly Springs, Lake, and Booneville.

Reports of directors and of treasurers of New Jersey Stations (*New Jersey Stas. Rpt. 1893, pp. 1–16, 191–199, 203–206*).—Brief general remarks on the work of the year, treasurers' reports for 1893, and legislation relative to the station and fertilizer control.

Work of American experiment stations, E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 42–44*).—A brief survey of the experiment station movement in this country, with remarks on the scope and purposes of station work, and the value of their studies and investigations from a practical and scientific point of view.

Report of observations made on European agricultural schools and experiment stations, 1892–'93, E. W. HILGARD (*California Sta. Rpt. 1893 and 1894, pp. 27–41*).—An interesting account of observations made in Germany and Switzerland.

MISCELLANEOUS.

The beginnings of agriculture, L. BOURDEAU (*Pop. Sci. Monthly, 1895, Mar., pp. 678–688*).

Socialism and agriculture in France, D. ZOLLA (*Ann. Agron., 21 (1895), Nos. 2, pp. 49–75; 3, pp. 97–122*).

Agriculture in the immediate vicinity of Berlin, ORTH (*Jahrb. deut. landw. Ges., 9 (1894), pp. 132–136*).

Notes on the agricultural features of the Congo, F. HAMBURSIN (*Ingén. Agr. Gembloux, 5 (1895), No. 7, pp. 325–330*).

Crops and live stock in Ontario (*Ontario Bureau Industries Bul. 52, pp. 16*).—Statistics on the condition of crops, live stock, etc., with extracts from returns of correspondents.

NOTES.

Arizona Station.—A greenhouse 24 by 80 ft. is in process of construction. At the Mesa substation deciduous, fruit, and ornamental trees have been planted, and at the Willcox substation tests are about to be made of pumping with a gasoline engine for irrigation purposes.

Indiana Station.—George R. Ives, formerly assistant agriculturist, has severed his connection with the station.

New Hampshire College.—On March 14 the college herd was reduced by the sale of 25 head at public auction. All the animals thus sold had been twice subjected to the tuberculin test. The State legislature has appropriated the sum of $25,000 to be expended by the College of Agriculture and Mechanic Arts in the building and furnishing of a residence and industrial hall for women.

South Dakota Station.—At the January meeting of the regents of education, J. H. Shepard, chemist of the station, was appointed director, *vice* Lewis McLouth, relieved; H. B. Mathews, meteorologist, was made assistant chemist, and the station council was reorganized and its powers and duties somewhat enlarged. Its number has been increased by the addition of one member from each of the governing boards, G. J. Coller being elected regent member and O. T. Grattan trustee member. L. C. Corbett, horticulturist, has been elected secretary and vice director of the council.

Wisconsin Station and College.—The following changes have been made in the governing board of the station: H. B. Dale, C. Keith, and N. D. Fratt have retired and are succeeded by O. H. Fethers, of Janesville; F. W. Challoner, of Oshkosh, and W. A. Jones, of Mineral Point.

The board of instruction of the college has been changed as follows: C. H. Diener has been appointed assistant in agricultural physics; F. E. Baker, assistant in judging live stock; F. Cranefield, assistant in horticulture; G. P. Pfeiffer, assistant in farm dairying; A. J. Schoenmann, assistant in milk testing; W. A. Voigt, instructor at pasteurizer; and T. A. Stanley, instructor in farm bookkeeping, has been succeeded by O. M. Taylor; E. J. Bennet, instructor in farm dairying, has been succeeded by J. D. Clark; W. E. Doane, instructor at butter worker, by F. B. Fulmer; E. H. Hageman and F. Walker, instructors at separators, by L. P. Biddick and J. A. Robinson; and J. E. Knott and F. Wismer, instructors in cheese making, by Julius Bird and John Kelty.

EXPERIMENT STATION RECORD.

VOL. VI. No. 10.

Efforts are continually being made in certain parts of Europe to discredit American clover seed. During the last two or three years, on account of the drought in Europe during the summers of 1893 and 1894, the importation of American seed greatly increased and an outcry was made to beware of such seed on account of insect larvæ, weed seeds, and general worthlessness. Some of the statements published seem to be inspired, not so much from a desire to protect consumers from real danger, as to bring the products of this country into disfavor.

The danger of introducing insect pests is very remote, and the purity and vitality of American clover seed will compare favorably with that grown in any part of the world. A prominent exporter has recently said that clover seed is sold abroad almost entirely by sample and that qualities are furnished to suit the intelligence and conscience of the buyers, hence the responsibility of placing a low grade of seed on foreign markets rests upon the importer. American dealers send their seed to the Federal Seed-Control Station at Zurich, Switzerland, for certification, and it ranks with that of any country in purity, vitality, and intrinsic worth. That weed seeds are found in American clover seed is not to be denied, but the same is true of European seed. Two lots of white and yellow clover seed, varieties little grown for seed in this country, reported upon in a recent Austrian report, contained 19 and 21.6 per cent of foreign seeds, a considerable proportion of which was clover dodder, a plant more injurious to clover than all the native weeds found in our clover fields.

In an article published in a reputable German agricultural journal, a list is given of 50 species of weed seed said to have been found in American clover seed. Thirty of the species enumerated are of European origin and 9 are not specifically determined, leaving but 11 species of certain American origin. The same author attempts to determine the part of the United States in which the clover seed grew from the accompanying weed seed. In making the city from which the seed was exported stand for the group of States adjacent to it he shows ignorance of the trade conditions of this country. He claims that seed of *Phacelia tanacetifolia* was found in considerable quantity in clover seed received from Baltimore, and that this seed is characteristic of the Atlantic group of States when in reality the plant is a Pacific Coast form.

In a later article he has determined a lot of seed as belonging to some member of the order *Tiliaceæ*, but from the description and figures given it is plainly not the seed of *Tilia*, and the only other genera in this country of this order, *Corchorus* and *Triumfetta*, are not grown in the regions producing clover seed. He insisted for a time that seed of *Rumex acetosa*, a pernicious European weed, were to be found in nearly all American-grown seed. Fortunately for us he was mistaken in the determination, as this weed has but a limited distribution in this country. Other of his determinations are doubtful.

That foreign seed is not above suspicion may be seen from reports of the various European seed-control stations, where it is shown that seed of high quality has been mixed with old seed which has been colored or with finely crushed colored quartz. American ingenuity has devised machines for cleaning seed that are said to be superior to any others, and importers can readily obtain American clover seed of good quality if they desire to do so.

By a recent order of the Secretary of Agriculture a dairy division is to be organized in the Bureau of Animal Industry for the purpose of collecting and disseminating information relating to the dairy industry of the United States. Maj. Henry E. Alvord, formerly president of the Maryland Agricultural College, who is widely known for the prominent part he has taken in promoting the interests of agricultural education and investigation in this country, and who has a high reputation as an expert in dairy matters, has been appointed chief of the new division.

THE PHYSICAL PROPERTIES OF THE SOIL.[1]

DR. EWALD WOLLNY.

PART 2.

III.—THE BEHAVIOR OF THE SOIL TOWARD WATER.

The moisture of the soil comes partly from atmospheric precipitation, partly from ground water. With a given amount of water the degree of saturation of a soil may vary widely, depending upon (1) physical condition, (2) depth, (3) position, (4) covering of the soil, and (5) course of the meteorological elements.

INFLUENCE OF THE PHYSICAL CONDITION OF THE SOIL.

In this connection we must consider the various causes which bring about the numerous complicated processes in the soil.

Conduction of water in the soil.—If we suppose the soil to possess a separate grain structure, the spaces between the grains may be regarded in their continuity as tubes, which possess capillary properties if the particles are sufficiently small. The capillarity ceases when the diameter of the particles is more than 2 mm., and varies with smaller particles than these to a greater or less extent according to the fineness of the grains.

With regard to the height to which water can be lifted from a lower layer, and to the velocity with which this occurs, there is the general law that water will be lifted the higher and the more slowly the finer the soil particles and the richer the soil in colloid ingredients. Different soils vary widely in this respect. Capillary height for clay often exceeds 2 meters, but for sand of medium fineness it is generally less than 0.4 meter. While, however, the maximum height is soon reached in sands, the rise in clays is very slow.

Similar behavior is observed in the conduction of water supplied from above. The percolation of water through the soil meets with a certain amount of resistance, due partly to capillarity, partly to adhesion and friction between the water and the soil particles, all of which increase with the fineness of the grains and the quantity of the colloid substances present. Hence the depth and velocity of the percolation are inversely proportional to the size of the grains and the richness of the soil in colloid substances.

---

[1] Continued from p. 774.

The large spaces occurring in tilled soils retard the capillary rise of water, but, on the other hand, increase the velocity with which water penetrates downward from the surface, often to a remarkable degree. If crumbly soils are pressed together (rolled), the upward movement of water is increased in proportion to the increase in density, but the percolation of atmospheric water is retarded. The presence of stones diminishes the capillary rise of water in the soil in proportion to the quantity of stones present, and the same is true of the percolation of water.

In soils which are made up of layers of different physical constitution the passage of water from one layer to another, either upward or downward, is hindered more and stopped sooner the wider the difference between adjacent layers in the fineness of their particles or in their other physical properties. Water rises or sinks from a coarse-grained to a fine-grained layer much more readily than the reverse.

The capillary movement of water in a soil occurs only when considerable water is present. It ceases when the soil contains 30 to 50 per cent (according to the fineness of the particles) of the quantity of water required for saturation, and instead there is a very much slower movement of water from the surface of one particle to that of another. If the water envelopes are diminished beyond a certain limit the movement of water ceases altogether.

Capillary rise and percolation of water in the soil declines as the water content of the soil diminishes, because the so-called surface tension of the liquid increases at the same time.[1]

The water-holding capacity of the soil.—The quantities of water in soils are best expressed in percentages of the volume of the soil occupied by water. The old method of expressing the water in percentages by weight is misleading on account of the variations in the specific gravity of soils.[2]

After movement ceases water is retained in the soil by surface attraction and also by the affinity of the colloid substances for water. Other things being equal, the quantity of water stored up by the soil is greater the finer the soil particles and the greater the quantity of colloid material present.

Phys., 14, p. 254. E. Wollny, Ibid., 7, p. 269, and 8, p. 206.

[2] A. Mayer, Landw. Jahrb., 1874, p. 753.

On examining a moist column of soil, in which movement of water has ceased, it is found that the quantity of water increases on descending, and that above a certain height the quantity of water remains constant. The reason of this is that in the upper part the water is held only by surface attraction and the capillarity of the very fine interstices, while the water flows out of the larger spaces. In descending the column increasing amounts of water are held even by the larger interstices until finally if the particles are sufficiently fine the water is held even in the largest interstices and the soil is saturated. For this reason we distinguish between an absolute or minimum water capacity, representing the quantity of water held in the upper part of a sufficiently high column of soil by adhesion and in the finest capillaries, and a complete or maximum saturation, representing the quantity of water held by the soil when all the intergranular spaces are filled.[1]

The variations in maximum capacity for water in different soils, with the exception of extremely coarse samples, are comparatively small, because the spaces are approximately equal. (Compare p. 764.) On the other hand, the volume per cent of water corresponding to the minimum water capacity is remarkably variable in natural soils, and generally shows a considerable difference from the maximum capacity. The values for the two kinds of water capacity approximate only in soils which have very small particles and are rich in clay and humus. From these facts it will be seen that the maximum is of much less interest than the minimum water capacity in forming a judgment of a soil.

The minimum water capacity increases, other conditions being equal, with the fineness of the soil particles and the proportion of colloid substances present. It is diminished considerably by the formation of aggregates and increased by compressing the soil. Stones diminish the water capacity. With an increase of temperature the water capacity diminishes owing to the decrease in the viscosity of the water. Repeated freezing and thawing of the mass cause changes in the mechanical structure of clay soils which result in a lowering of the water capacity.[2]

Permeability of the soil for water.—This is very closely connected with the properties already described. It is this property of soils therefore which prevents their supersaturation.

Other things being equal, the quantity of water which filters through a soil may be considered a measure of its permeability. Experiments on this property have shown that the permeability of the soil for water increases with an increase in the size of the grains and a decrease of the quantity of colloid substances present. Clay, humus, and very fine sand, and concretions formed by precipitation (carbonate of lime, hydrated oxid of iron) or adhesion of particles (hardpan) are almost completely impervious to water. The high permeability of coarse soils may be considerably diminished by an admixture of fine-grained material. In stratified soils the permeability is controlled by that layer which is made up of the finest particles, even when the layer is thin. In crumbly soils the permeability is considerably greater than in powdery soils, and it decreases in loose soils when they are pressed together.

Mayer, Fühling's landw. Ztg., 1875, p. 18. H. von Klenze, l. c., p. 122. E. Wollny, Forsch. Geb. agr. Phys., 8, p. 177.

The quantity of water passing through the soil increases with the water pressure—not in the same proportion, but to a less degree. However, the differences in the quantity of water for a given material and thickness of layer corresponding to equal intervals of pressure are constant. Experiments have shown, further, that in fine-grained soils and at high pressures the quantity of water passing through the soil diminishes as the thickness of the layer increases; while in other soils and under lower pressures the relation of the quantity of water to the thickness of the layer is not as great, diminishing as the size of the grains increases.[1]

The power of evaporation of the soil.—This is most conveniently measured by the quantity of water given off by evaporation to the atmosphere from the unit of surface. The method of referring the evaporation to the weight of the soil is subject to the same objections urged against the determination of the water capacity according to the weight of the soil.

The quantity of water evaporated, where only the physical structure of the soil is considered, depends on (1) extent to which the factors determining evaporation (temperature, moisture, and movement of the air) exert their influence, and (2) the power of the lower layers of soil to supply the loss at the surface.

Evaporation increases with the extent of surface. Therefore the quantities of water given up to the atmosphere are greater from uneven and rough than from smooth surfaces. Evaporation is greatest from a southern exposure, next greatest from an eastern, next from a western, and least from a northern exposure. The quantity of water evaporated increases on a southerly and decreases on a northerly exposure with the inclination. For easterly and westerly exposures the influence of inclination on evaporation is hardly perceptible. When very wet, dark soils lose more water by evaporation than light-colored ones, but for dryer soils the reverse is the case.[2]

R. von Schwarz, Erster Bericht über Arbeiten der k. k. landw.-chemischen Versuchs-Station in Wien, 1878, p. 51. F. Seelheim, Archives Néerland. Sci. Exact. et Nat., 14, p. 393. D. von Welitschkowsky, Arch. Hyg., 2, p. 499. E. Wollny, Forsch. Geb. agr. Phys., 14, p. 1.

[2] C. Eser, Forsch. Geb. agr. Phys., 7, pp. 46, 47, 53, 97.

The influence of the physical structure of the soil on the evaporation is readily understood if the processes taking place are closely examined. If the water present at the surface of a wet soil passes into the atmosphere in the form of vapor, the pores near the surface are gradually emptied and the water in the next layer forced toward the surface. When this process is communicated to the layers farther down, an upward movement of water by capillarity occurs in the whole mass. In consequence of this process the quantity of water present in the soil diminishes until capillary movement ceases. From this point the water lost from the surface is no longer replaced, and the only remaining movement is that of water from particle to particle on their surfaces, which is very slow. In consequence, the surface of the soil dries up. The uppermost dry layer now hinders the direct influence of the agencies of evaporation, especially that of the wind. Evaporation, therefore, decreases rapidly after the upper layers dry up, and the resistance increases as the drying proceeds downward.

From the above it will be seen that the evaporation steadily decreases under long continued dryness, and further, that the more easily the evaporated water is replaced the more rapid is evaporation and the slower a dry layer is formed, and *vice versa.* It is clear that saturated (wet) soils, irrespective of their mechanical constitution, allow approximately equal quantities of water to evaporate, and that the rate of evaporation, other things being equal, rises and falls with the humidity of the soil. Hence the evaporation capacity of a soil is intimately connected with its water capacity, and is greater in proportion to the fineness of the soil and to its richness in colloid substances, and *vice versa.*

In crumbly soils the evaporation is less rapid than in soils of separate grain structure because in the former case the noncapillary spaces retard the rise of water. Stones act in the same way. An increase in density increases the capillarity, and consequently the evaporation.

In soils of different depths evaporation increases with the height of the soil column up to a certain limit and then diminishes again in proportion to the increase in height. If there is water underneath the soil the evaporation decreases as the distance between the surface of this water and that of the soil increases and as the capillary rise diminishes.[1]

Phys., 3, pp. 117, 325, 328; 4, p. 360; 5, pp. 21, 157; Landw. Jahrb., 1876, p. 457. C. Eser, Forsch. Geb. agr. Phys., 7, p. 1.

The quantity of water present in the soil at any time is due to the combined action of the factors described as affecting the humidity of the soil, as well as to other influences. In general, the average quantity of water in natural soils is greater in proportion to the fineness of the particles and the quantity of clay and humus present. Of the different soil constituents humus holds as a rule the largest quantity of water, then follow in order clay, loam, and quartz. Soils having a separate grain structure show a much higher average humidity than crumbly soils. Stones diminish the percentage by volume of water in proportion to their quantity. With an increase in density we generally find a rise in humidity, other things being equal.

As may be seen, the variations of humidity in natural soils correspond in general to those of water capacity, because as a rule evaporation and permeability practically equalize each other, for generally a high evaporation is associated with a correspondingly low permeability, and *vice versa*. Nevertheless, these factors, especially evaporation, can under certain circumstances weaken or completely nullify the influence of the others. For instance, the values for the average humidity of soils of varying compactness are more nearly the same than those found for the water capacity under the same circumstances, because with the increase in density the evaporation increases, involving a more rapid loss of the stored up water.[1] That evaporation is in many cases the most important factor influencing the humidity of the soil is shown by the fact that a soil of uneven surface and dark color contains less water than one of smooth surface and light color.[2] The stirring of the upper layer of soil at first increases the evaporation, but after a short time the loosened layer dries out and serves to prevent evaporation from the lower layers by diminishing the direct influence of the agencies of evaporation on the soil and by retarding the capillary rise of water to the surface.[3]

Variations in the humidity of the upper parts of the soil are caused by the accumulation of water in an impermeable layer in the subsoil. If this impermeable layer is near the surface, the water may come quite to the top of a level soil, in which case the soil is saturated. If the ground water is farther beneath the surface the influence on the humidity of the upper layers depends entirely on the conductivity of the layers. The higher the water rises by capillarity the greater the influence of the ground water on the humidity of the upper layers.

INFLUENCE OF THE DEPTH OF THE SOIL.

Experiments on this subject[4] have shown that the absolute humidity of the soil always increases with the thickness of the soil layer, and that the percentage by volume behaves in the same way up to a certain limit, above which it does not change with an increase in the depth of the soil. This limit varies considerably in different soils. It lies at that point where the capillary rise of water from the lower moist layers of the soil toward the surface ceases. It increases, therefore, with the ability of the soil to conduct water by capillarity, and *vice versa*. Variations in the humidity increase as the thickness of the soil diminishes.

[2] Ibid., 3, p. 117; 12, p. 386.

[3] Ibid., 3, p. 325.

[4] Ibid., 16, p. 1.

INFLUENCE OF THE POSITION OF THE SOIL.

Inclination.—A level soil is, as a rule, moister than an inclined soil. If inclined, the moisture decreases with an increase in inclination. In the case of inclined soils the difference in moisture in the higher and lower parts of the soil increases with inclination.

Exposure.—In soils having different exposures, those facing the north have most moisture, then those toward the west, then the east, while those facing the south are driest. These differences increase with the angle of exposure.[1]

INFLUENCE OF THE COVERING OF THE SOIL.

The moisture content of a soil covered with plants during the period of growth is always lower, under like conditions, than one left bare. This is due to the rapid transpiration of water by living plants. This drying up of the soil, which is also noticed in timber lands, is greater in proportion to the development of the plants, the thickness of the stand, and the length of the period of growth. The influence on the humidity of the soil diminishes as the plants die off on approaching maturity, and is greatest when development of the aërial organs is greatest.

A covering of dead plants, straw, stable manure, etc., or of such materials as stones, gravel, wood, etc., increases the moisture of a soil during the warm seasons, because such a covering affords protection against evaporation. In general the moisture of the soil increases with the thickness of such a covering.

We see, then, that as a rule soils shaded by growing plants contain least moisture, soils covered with stones and other lifeless materials contain most, while those that are bare stand intermediate.[2]

Phys., 11, p. 299; Forstliche Bodenkunde, 1893, p. 255.

This can not be disregarded if we wish to obtain a clear insight into the cause of the widely varying condition of moisture of soils under natural conditions, because the physical properties of the soil itself are influenced by the average course of the elements (climate) and their behavior at different times (weather).

The effects of climate may be thus generally stated: A higher degree of moisture in the soil accompanies copious precipitation, greater humidity of the atmosphere, moderate movement of the air, lower temperature and greater water capacity of the soil, while a drier condition of the soil is caused by the reverse circumstances. For a particular case the effects can only be understood by knowing the course of the individual elements and the constitution of the soil.

The relation of the weather to the humidity of the soil is many sided.

Although the quantity of precipitation in the countries of middle Europe is smaller during the cold season than during the warmer parts of the year, the wetting of the soil is very much more complete in the former than in the latter case on account of the diminished evaporation due to a lower temperature. This is particularly true of soils covered with plants, because the latter, as a rule, use up the water obtained by the soil from the atmosphere during the period of growth, and sometimes a part of the water stored up during the cold season also.[1] From these facts it follows that the water collected in the soil during the period of no growth (winter moisture) may, under certain circumstances, be very important for vegetation.[2]

In the dry season the influence of evaporation is as a rule predominant. In long periods of dryness evaporation may cause an equalizing of humidity in soils of different physical constitution, independently of how high the moisture was originally.[3] The differences in humidity between covered and bare soils show themselves more strongly, however, under such circumstances. This is also true for uneven, dark-colored soils, compared with smooth light-colored soils.[4]

Winds influence evaporation to a remarkable degree, and therefore exert a great influence on the humidity of the soil. The evaporation varies with the velocity of the wind. In the case of westerly and northerly winds, which are moist as a rule, the evaporation is less than in the case of easterly and southerly winds, which are generally dry.[1] [This, of course, is not universally true.—ED.]

During the rainy period the precipitation serves first to replace the water evaporated during the preceding period—that is, to remoisten the soil. The saturation of the soil takes place in different ways according to the conductivity and water capacity of the soil. Fine grained soils which conduct water slowly are only moistened to a slight depth, and in consequence of this the water accumulates to a greater or less extent on the surface in the case of level land, or flows away if the ground is sloping. Soils of this kind store up during a copious precipitation of long duration more water than corresponds to their water capacity, because the water percolates slowly. The greater the permeability of the soil the easier the water sinks and the thicker the layer of soil which is moistened. A high degree of permeability, therefore, lessens the storage of water, since more or less of the rainfall passes down into the depths of the soil. Soils of this kind are most uniformly moistened when there is at each precipitation not more water than the soil can retain. From this we see the importance of greater frequency of precipitation for such soils. The need of frequent precipitation decreases as the water capacity increases and permeability decreases, because the water supplied to the soil is stored up to a greater or less extent. In extreme cases—that is, with difficultly permeable soils—a less frequent but more copious supply of water must be regarded as more advantageous.[2]

In as far as the humidity depends on the texture of the soil, the quantity of water stored up during the wet season corresponds almost exactly to the water capacity of the soil. When, on the other hand, the differences in soil moisture are caused by those in evaporation, precipitation may cause an equalization of the quantities of water stored up. Therefore the variation in soil moisture due to difference in character (evenness, color) of the surface, or to difference in covering, exposure, and inclination, may during long rainy periods or the colder seasons become more or less completely equalized.

From the fact that the atmospheric precipitation serves first to replace the water lost by evaporation during a period of dryness, and that an excess sinks down or collects only when the soil is saturated, we must infer that the quantity of percolating water and the height of the ground water can not be ascertained from the permeability of the soil or quantity of precipitation alone. The general facts in this connection are summarized below.

THE QUANTITIES OF PERCOLATING WATER.

In soils destitute of plant life the quantity of percolating water varies with the atmospheric supply, but in a ratio which depends on the physical structure of the soil, character of its surface, distribution of the precipitation, and the season. The greater the evaporation and the water capacity and the less the permeability of the soil, the smaller is the quantity of percolating water, other things being equal. For these reasons percolation diminishes in proportion to the increase of fine particles (clay and humus) in the soil or to the decrease of large noncapillary spaces, and *vice versa.* The downward flow of water increases with the thickness of the soil layer up to a certain limit (about 60 cm.), above which an increase in thickness is without influence on percolation. In the case of light-colored, loose, and even surfaces the percolation is greater than in dark-colored, compact, and uneven surfaces. The covering of a soil with lifeless material (dead plants, stones, coarse-grained soils) causes a considerable increase, while a covering of living plants causes a remarkable decrease in the amount of percolating water. The influence of the distribution of precipitation on the absolute quantity of water carried off from beneath the surface is shown in the fact that the largest quantities of percolating water in bare soils occur in seasons of greatest precipitation. Those districts where the soil freezes and becomes impermeable in winter form an exception to this rule. In such cases drainage is generally suspended until the spring. With regard to the ratio of the water percolating through the soil to the quantity of precipitation, it is generally true that relatively the larger proportion of the water supplied is carried away by drainage when the season is coldest. In soils covered with living plants the quantities of percolating water do not follow the course of precipitation, but are greatly reduced by transpiration by plants. For these reasons the greatest percolation occurs in all cultivated regions irrespective of the distribution of moisture in the cold season of no growth, in winter or in spring, according to the predominance of warmth.[1]

[2] E. Wollny, Forsch. Geb. agr. Phys., 14, p. 138. Compare also p. 853.

THE HEIGHT OF THE GROUND WATER.

Variations in the height of the ground water depend partly upon the physical structure of the soil, partly upon the quantity and distribution of precipitation. In horizontal strata the height of the ground water depends upon the depth of the impermeable subsoil, and approaches nearer to the surface of the soil in proportion to the coarseness of the soil and its poorness in clayey and humus materials. In periods of drought the variations in the level of the surface of the ground water increase with the thinness of the permeable layer in which the water occurs, and with the ease with which the water is raised by capillarity. In bare soils and in those covered with lifeless materials the ground water rises and falls with the quantity of precipitation so long as the water table does not reach the surface. In soils covered with living plants no ground water collects during the period of growth even when the soil is very deep (1.2 meters or more), or at least only temporarily.[1]

Phys., 10, pp. 1, 321; 17, p. 180.

THE DISTRIBUTION OF WATER IN THE SOIL.

From what has been already said it is readily understood that the moisture, as a rule, increases with the depth. This is true of all soils as long as there is no precipitation and no downward movement of water. In case of a soil of low permeability or one covered with strongly transpiring plants a thorough moistening of the upper layers occurs only when atmospheric moisture is supplied. Under these circumstances more water is contained in the upper layer temporarily than in the lower strata, and a dry layer may occur between the upper and lower moist layers if the rain is not sufficient for complete saturation—an occurrence observed quite frequently in soils covered with plants during the summer.

According to Hofmann[2] we may conveniently distinguish three soil layers. First there is a superficial zone of evaporation, in which the degree of moisture varies from complete saturation to great dryness. In this zone in case of a dry, hot summer the whole of the summer and late autumn precipitation may often be absorbed without filling up the capillary pores down to the lower limit of the zone. In such cases an intermediate dry layer always exists between the upper layer, temporarily moistened by precipitation, and the deeper water-conducting layer. Below this superficial zone, then, there lies the so-called transition zone, which is that part which is never dried up, but which always has its capillary pores filled with water. If this second zone receives water from above after the superficial layer has been completely saturated with water it does not retain it, but allows the excess to sink into the third zone—that of the ground water.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The estimation of nitrogen in feeding stuffs by the Kjeldahl method, GERLACH and SÜVERN (*Chem. Ztg., 18 (1894), No. 97, pp. 1902, 1903*).—A number of determinations of nitrogen by the Kjeldahl method in cotton-seed meal, rice meal, and peanut meal showed that varying the time of digestion from 2 to 12 hours caused an increase of scarcely 0.1 per cent. The use of concentrated sulphuric acid containing 150 gm. of phosphoric anhydrid to the liter secured practically the same results. The average of a number of blank determinations showed that about 0.03 per cent of nitrogen was obtained from the air in the digestion flask after 12 hours' digestion. The authors therefore conclude that the use of phosphoric anhydrid is unnecessary, and that a digestion of from 2 to 3 hours is sufficient. The small additional amount of nitrogen obtained after a long digestion is doubtless from some compound other than albuminoids and would play a small part in the economic value of the feeding stuffs.—J. P. STREET.

Note on the Kjeldahl method for nitrogen, O. KELLNER, O. BÖTTCHER, and G. DIESSELHORST (*Chem. Ztg., 19 (1895), No. 3, p. 35*).—An answer to the above article of Gerlach and Süvern, showing that the total nitrogen can not be obtained from products like cotton-seed meal by digesting from 2 to 3 hours unless the sulphuric acid contains phosphoric anhydrid and metallic mercury is added.—J. P. STREET.

On the preparation of ammonium citrate solution, R. DE ROODE (*Jour. Amer. Chem. Soc., 17 (1895), No. 1, p. 47*).—If in making the citrate solution it is made decidedly alkaline with ammonia and allowed to stand over night, in the morning the solution will be found to be strictly neutral. The addition of a small quantity of salicylic acid (1 gm. to 5 liters) before neutralizing will prevent the growth of fungus in the solution.—J. P. STREET.

Some facts observed in the determination of phosphoric acid by the molybdic acid process, R. DE ROODE (*Jour. Amer. Chem. Soc., 17 (1895), No. 1, pp. 43–46*).—Experiments are briefly reported from which the author draws the following conclusions:

"(1) Our present method [official] for determining phosphoric acid seems to give results which are somewhat too high.

"(2) The results obtained by using a large quantity of substance, and obtaining large precipitates, are lower and somewhat more accurate than those obtained where smaller quantities are employed.

"(3) Somewhat lower and more accurate results are obtained by using a blank made by employing a dilute solution of a phosphate, which is added to each determination. This blank, previously determined, being substracted from the final result.

"(4) Accurate results, agreeing with those obtained by the use of the blank, are obtained by redissolving the magnesium pyrophosphate and reprecipitating.

"(5) Five minutes' digestion at 65° C. seems to be sufficient for the complete precipitation of phosphoric acid by molybdic solution."—R. H. LOUGHRIDGE.

The determination of phosphoric acid, H. PEMBERTON, Jr. (*Jour. Amer. Chem. Soc., 17* (*1895*), *No. 3, pp. 178–181*).—The author calls attention to several points in his method (E. S. R., 5, p. 444). In preparing the standard alkali the indicator used should be phenolphthalein and not methyl orange, as the latter is affected by the alumina usually contained in potassium hydroxid. In heating the solution it should be brought to a full boil. It will then take care of itself and does not need any definite temperature for proper precipitation. In precipitating, the aqueous molybdate should be added slowly, stirring frequently, thus obtaining a purer precipitate.—J. P. STREET.

The determination of potash in manures, W. E. GARRIGUES (*Jour. Amer. Chem. Soc., 17* (*1895*), *No. 1, pp. 47–51*).—Work 10 gm. of the sample into a paste with concentrated sulphuric acid in a platinum dish. Ignite, raising the heat gradually until the residue is white, or red if iron be present. Grind the residue in a mortar to a fine powder, add a little hot water, and triturate the mass for a few minutes. Wash into a 500 cc. flask and boil with 250 cc. of water for 30 minutes, and then run in a 10 per cent solution of barium chlorid, 5 cc. at a time, boiling after each addition, until no further precipitation is visible. Add sodium carbonate until a faint permanent rose color is obtained with phenolphthalein. Boil for a minute, cool, and fill to the mark. Filter, add hydrochloric acid in slight excess to 50 cc. in a porcelain dish, and evaporate on a water bath with platinic chlorid. Wash the precipitate with alcohol (sp. gr. 0.848), dry at 100° C., and weigh. For potash salts, the ignition with sulphuric acid is omitted.

The sulphuric acid must be added cautiously to prevent loss from the violent reaction, when chlorids and nitrates are present. The ignited mass must be pulverized very finely, to prevent the occlusion of potash by the calcium sulphate. An excess of sodium carbonate must be avoided, as double decomposition may take place.

While the method does not, in common with those now in use, return quite all the potash, it is claimed that it is no less accurate, and gives less discordant results than the Lindo-Gladding, besides being more satisfactory to work and quicker. One filtration and evaporation only are entailed, but a greater quantity of platinic chlorid is required.—J. P. STREET.

The addition of calcium chlorid to the solution of a fertilizer in the determination of potash, R. DE ROODE (*Jour. Amer. Chem. Soc., 17* (*1895*), *No. 1, p. 46*).—Experiments made by the author indicate that in the presence of ammonia and some ammonium oxalate or carbonate the addition of calcium chlorid does not result in the formation of tricalcium phosphate in the solution prepared as directed in the official methods, and hence "the very object for which the calcium chlorid is added is defeated."

The determination of woody fiber in fodders, A. P. AITKEN (*Analyst, 20 (1895), Feb., pp. 35–37*).—The author follows the conventional method of digesting with 1¼ per cent acid and alkali, but overcomes the difficulties of frothing and change of strength by evaporation by abandoning boiling. "I now use beakers, which I immerse in a steam bath and which I cover with watch glasses. The result is that the solutions are maintained at the temperature of boiling water and no evaporation takes place, so that the strength of the solution does not alter and the subsequent washing of the residues and their final removal from the beaker to a filter or Gooch crucible is easy. The extraction of the soluble matters is not so rapid, . . . but three quarters of an hour in the steam bath is equivalent to half an hour's boiling." The conditions being more uniform, successive determinations "give results of great uniformity."

Extraction of the fat was mentioned as advisable in the case of oil cakes. In the discussion following the paper Mr. Dyer regarded incomplete extraction of the oil, either before or after treatment with acid or alkali, as a frequent source of error. Mere alkaline treatment failed to saponify more than a fraction, sometimes only a moderate fraction, of the oil.

Quick estimation of starch, P. L. HIBBARD (*Jour. Amer. Chem. Soc., 17 (1895), No. 1, pp. 61–68*).—Place enough of the finely pulverized material to contain at least 0.5 gm. of starch in a flask with about 50 cc. of water, and add 1 or 2 cc. of malt extract. Heat to boiling, shaking frequently to prevent the formation of clots of starch. (The addition of diastase before gelatinizing the starch helps to prevent this, as it acts above the temperature at which the starch becomes pasty.) After boiling a minute, cool to 50 to 60° C., and add 2 to 3 cc. malt extract. Heat slowly from 10 to 15 minutes till boiling, again partially cool, and test with iodin solution. If there is a blue reaction, another addition of malt must be made. When all the starch is changed, cool the mixture, make up to definite volume, and filter through fine linen or muslin. Place an aliquot part of the filtrate, containing 0.2 or 0.3 gm. of starch, in a 100 cc. flask with 5 cc. hydrochloric acid, containing 30 per cent of hydrochloric acid, and water to make about 60 cc. total. Boil for 30 minutes on a sand bath, cool, nearly neutralize with sodium hydroxid, and determine the dextrose by Fehling's solution. The method is said to be simple, rapid, and fairly accurate.—J. P. STREET.

Method of estimating acidity of milk, M. SCHAFFER (*Staz. Sper. Agr. Ital., 26 (1894), pp. 164–167; abs. in Jour. Chem. Soc., 67–68 (1895), Mar., p. 94*).—An apparatus is used consisting of 3 bulbs, 2 holding about 50 cc. each connected by a narrow graduated tube, and the third below holding 2 cc. The upper bulb is stoppered. In making a test 2 cc. of phenolphthalein is placed in the lowest bulb, then 50 cc. of milk, measured on the graduated tube, and 2 to 2.5 cc. one fourth normal soda solution, and mixed, not shaken. Soda is added until alkaline, and the quantity used is read off on the graduated tube connecting the 2 large bulbs.

The relation between specific gravity, fat, and solids-not-fat in milk, H. D. RICHMOND (*Analyst, 20 (1895), Mar., pp. 57, 58*).—A simplification of Richmond's new formula to

$$T = \frac{G}{4} + \frac{6}{5}F + 0.14,$$

in which T=total solids, G=lactometer reading, and F=fat.

"The results will not differ (in extreme cases) more than 0.02 from the other formula." The formula may be further simplified to

$$T = 0.25\ G + 1.25\ F, \text{ or } T = \frac{G+5\ F}{4}$$

"and this second formula is correct within 0.2 per cent up to 6 per cent fat. It is still more accurate if 0.05 per cent be added for each 1 per cent above 3 per cent, and subtracted for each 1 per cent below 3 per cent."

The detection of saccharin in beer, F. GAULTER (*Rev. Internat. Falsif., 8 (1894), p. 47; abs. in Chem. Centbl., 1895, I, No. 3, p. 175*).—The author finds that the resin present in beer produces a fluorescence when treated with resorcin and sulphuric acid, and for this reason holds that Börnstein's reaction is uncertain. To obviate this difficulty he evaporates to a sirup, adds a few drops of hydrochloric acid, extracts with 95 per cent alcohol, evaporates the alcoholic extract to a sirup, extracts with ether, and evaporates to dryness. The residue is then extracted with hot water, and the saccharin obtained from the water as a yellowish crystalline substance.—W. D. BIGELOW.

Notes on the estimation of iron and alumina in phosphates, K. P. MCELROY (*Jour. Amer. Chem. Soc., 17 (1895), No. 4, pp. 260–263*).

Contribution on the estimation of nitric acid, R. BERGER (*Chem. Ztg., 19 (1895), No. 15, pp. 305, 306*).—A volumetric method based on the same principle as the Schulze-Tiemann. The method has been successfully used in the analysis of saltpeter, and in the determination of the amount of nitric acid in sulphuric acid.—J. P. STREET.

The determination of potash in kainit, R. DE ROODE (*Jour. Amer. Chem. Soc., 17 (1895), No. 2, p. 85*).—The evaporation of "an aliquot portion of a filtered aqueous solution of kainit directly with platinum chlorid" is claimed to give accurate results.

The oxidation of organic matter and the decomposition of ammonium salts by aqua regia in lieu of ignition, in the determination of potash in fertilizers, R. DE ROODE (*Jour. Amer. Chem. Soc., 17 (1895), No. 2, pp. 86, 87*).—The details of the method have not yet been worked out.

On the determination of cane sugar in the presence of commercial glucose, H. A. WEBER and W. MCPHERSON (*Jour. Amer. Chem. Soc., 17 (1895), No. 4, pp. 312–320*).—This article appeared originally in the Proceedings of the Association of Official Agricultural Chemists for 1894.[1]

BOTANY.

The action of the water of the soil on vegetation, E. Gain (*Rev. gén. Bot., 7 (1895), Nos. 73, pp. 15-26; 74, pp. 71-84; 75, pp. 123-138, figs. 2*).—The author reviews his own work and that of other investigators in the following lines: (1) The amount of water in arable soils, (2) physical and chemical action of water on the substances which plants assimilate from the soil, and (3) the biological effects of dryness or humidity of the soil.

It is pointed out, among other things, that the moisture of the soil has a marked influence upon the activity of the microörganisms of the soil which aid in the nutrition of plants, especially the root tubercle bacteria.[1] The author's experiments lead to the conclusion that a medium amount of moisture in the soil (50 per cent of that required for complete saturation) is as a rule more favorable to the development of root tubercles than higher or lower amounts.

The results of experiments relating to the biological effects of dryness and humidity on 6 different kinds of soils indicate that different plants behave in the same manner as regards resistance to drought, but that the amount of moisture destructive to plants varies with the stage of growth. It is possible, therefore, to trace a curve for each species, showing its water requirements at every period of growth.

As regards the influence of the moisture of the soil on absorption and transpiration by plants, experiments indicate that (1) the saturation of a soil previously dry produces marked disturbances in the flow of sap; (2) transpiration varies with the water content of the soil, being greater the higher this content; and (3) when the maximum of turgescence is passed transpiration decreases, there being in fact a maximum of turgescence for each moment of growth at which the functions of nutrition are most active.

The effect of decapitation on plant organs, B. ROTHERT (*Trans. Assn. Naturalists, Imp. Univ. Kazan, 26 (1893), No. 5, p. 77, figs. 2*).—The present investigations were conducted by the author to test the statement of Darwin that the cotyledons of *Phalaris canariensis*, the tops of which had been cut off, did not undergo any heliotropic curving, while those which were uninjured curved rapidly and strongly; from which Darwin concluded that the top of the cotyledon was sensitive to light and that heliotropic curving of the lower part of the cotyledon is caused by irritation transmitted to it from the top, and that the loss of heliotropism was due to removal of the sensitive part of the shoot.

Following the methods of experiment pursued by Darwin the author conducted a series of experiments with etiolated plants of *Phalaris canariensis*, in which he proved that decapitation produces but a temporary disappearance of heliotropic curving.

A second series of experiments was conducted with *Avena sativa* and also *P. canariensis*, in which the action of the two are so nearly alike that they are described together. From 4 to 7 mm. of the tips were cut from the oats, and from the canary grass the portions removed varied from ½ to 7 mm. The experiments proved that the disappearance of heliotropic curving was evidently produced by the wounding of the shoots and is not to be attributed to the removal of the irritating effect when the top is cut. The belief that the disappearance of heliotropic curving might be due to temporary arresting of growth of the rest of the shoots caused the author to conduct a series of experiments in which various zones were marked off on the growing shoots, and the growth of uninjured and decapitated shoots compared. From the experiments it is shown that decapitation always causes considerable decrease of growth. This decrease is most marked in the zone nearest the cut, where in some cases there is no growth shown, but on descending toward the base of the shoot the difference between the growth of the decapitated and sound plants becomes greatly reduced. It was also shown that the decrease in growth was the strongest at the beginning of the experiment and became less as the later measurements were made. Decapitation decreases the normal rate of growth fully one fourth, and this reduction in growth will be shown in the diminished curvature when compared with the normal rate of growth in shoots which causes strong curving in a few hours.

---

[1] Compt. Rend., 116 (1893), No. 24, pp. 1394–1396 (E. S. R., 5, p. 112).

The author conducted a series of experiments to determine why the decapitated plants did not undergo heliotropic curving. A number of plants in which heliotropism had been induced were decapitated and compared with uninjured shoots, showing that it was due to decapitation temporarily destroying the heliotropic sensitiveness. The remaining part of the shoots is insensible to the irritation caused by one-sided illumination. Decapitation in this case caused a strong diminution in the rate of growth, and temporarily caused a total loss of sensitiveness toward external irritants.

A series of experiments was conducted in which vertical incisions in or near the top of the cotyledon were made to ascertain whether this form of injury would have the same effect on heliotropism as decapitation. But little effect was noticed, showing, in the author's estimation, that the phenomena described above are not due to the wounding of the shoots, but are to be attributed exclusively to the removal of the connection between the top and the remaining body of the cotyledon.

Since the specific irritation produced by decapitation acts downward from the cut along the cotyledon, the author made some experiments to ascertain whether this irritation is transmitted to any considerable distance or whether its effect is circumscribed within narrow limits. He found that if the top is cut off for several millimeters the action extends over the entire length of the shoots; but if ½ to 1 mm. is removed the action is carried to a much less distance, the time which transpires before the effect of decapitation manifests itself varying from 3 to 6 hours, and the heliotropic sensitiveness of the decapitated shoots was reëstablished within 24 hours. The characteristic unequal distribution of the sensitiveness of the shoot was arrested and the upper end became more sensitive than the lower part, showing that a regeneration of the injured top had taken place in the upper end of the decapitated shoot as soon as the physiological properties of the normal top were restored, proving that these properties do not reside in any definite morphological part of an organ and are not connected with any definite anatomic structure. It is further shown that shoots decapitated after the induction of heliotropism become not only insensible to heliotropic irritation, but also to geotropic, and that decapitation has the same effect on geotropism of shoots as it has upon heliotropism.

Experiments were conducted which showed that the loss of geotropic curving is due to the loss in rapidity of growth and also the loss of geotropic sensitiveness. Experiments by the author show that the top of the cotyledon possesses a very strong geotropic sensitiveness, and that being concentrated at or near the top of the cotyledon it must be admitted that the geotropic irritation is transmitted downward from the top along the cotyledon. Otherwise the geotropic and heliotropic curving would have been different instead of showing the same phenomena.

The author's conclusions are that decapitation of the cotyledons of *Gramineæ* (*Avena sativa, Phalaris canariensis, Setaria viridis*) causes two effects independent of each other, namely, a strong retardation of growth, and the loss of geotropic and heliotropic sensitiveness. If the top is cut from plants where heliotropism and geotropism has been induced in the shoots the curving is due to after action and they will not respond to the new action of irritants. The effects of decapitation last but a few hours, after which the rapidity of growth as well as susceptibility to irritants are gradually restored and at the end of 24 hours become altogether normal. Experiments on *Avena sativa* show that the previously unequal distribution of heliotropic sensitiveness is destroyed. In experiments with shoots of *Brassica napus* decapitation produced effects essentially the same so far as the principles involved are concerned.

Conçerning copper from the standpoint of toxicology, A. TSCHIRCH (*Das Kupfer vom Standpunkte der gerichtlichen Chemie, Toxikologie und Hygiene; abs. in Chem. Ztg., 18 (1894) No. 102, Repert., p. 329*).—The author, contrary to the opinions of many others, says that copper is not injurious to plants. The salts of copper, such as the sulphate, chlorid, nitrate, etc., are corrosive and do exert an injurious effect on plant life. Plants grown in soil that contained insoluble copper compounds are said to have taken up some of this copper without any injury. Water cultures of *Phaseolus multiflorus* were grown in nutrient solutions containing 2 gm. of copper oxid to every 3 liters of the solution. The roots were thoroughly aërated from time to time and no injury was apparent to the plants. Experiments were made with 36 culture plants under the above conditions and their growth was stronger and the plants appeared more vigorous than parallel cultures where the nutrient solution contained no copper.

Synopsis of North American Amarantaceæ, II, E. B. ULINE and W. L. BRAY (*Bot. Gaz., 20 (1895), No. 2, pp. 155–161*).—A revision of the species of *Acnida* and *Gomphrena* is given.

A revision of the genus Cordyceps, G. MASSEE (*Ann. Bot., 9 (1895), No. 33, pp. 1–44, pls. 2*).—The author enumerates 62 species, one of which, *C. velutipes*, is described as new. Of those fully described 22 species are peculiar to the Old World, 23 to the New World, and 6 are common to both.

A popular treatise on the physiology of plants, P. SORAUER (*Translated by F. E. Weiss. London and New York: Longmans, Green & Co*).

Anatomy of the leaves of Arctic plants, F. BOERGESEN (*Jour. Bot. France, 9 (1895), No. 1, pp. 1–7; No. 2, pp. 21–27*).—In the main the conclusions are the same as given by G. Bonnier (E. S. R., 6, p. 616).

A contribution to the comparative anatomy of coniferous fruits, M. RADAIS (*Ann. Sci. Nat. Bot., 19 (1894), No. 3–6, pp. 165–368, pls. 15*).

Aërial roots of carnations, B. D. HALSTED (*Garden and Forest, 8 (1895), pp. 158, 159*).—An account is given of the presence of aërial roots on carnations. The author thinks their presence was probably due to surplus moisture as well as a tendency of some individual plants to throw out such roots.

Concerning the opening mechanism of flowers, C. STEINBRINCK (*Ber. deut. bot. Ges., 13 (1895), No. 2, pp. 55–61, figs. 5*).

Concerning the opening and closing of flowers, F. OLTMANNS (*Bot. Ztg., 53 (1895), I, No. 2, pp. 31–52*).

The spontaneous movements of leaves of the Leguminosæ and Oxalideæ, A. RODRIGUE (*Bul. Soc. Bot. France, 41 (1894), pp. CXXVIII–CXXXIV*).

The functions of the beards on barley, A. ZOEBL and C. MIKOSCH (*Sitzungsber. kgl. Akad. wissensch. Wien, 1892; abs. in Ann. Agron., 21 (1895), No. 3, pp. 143, 144*).

Concerning the structure and arrangement of the laticiferous tissue with special reference to gutta-percha and caoutchouc bearing plants, O. CHIMANI (*Bot. Centbl., 61 (1895), Nos. 10, 11, and 12, pp. 353–360, 385–395, and 417–426*).

Some factors influencing the health of plants under glass, B. T. GALLOWAY (*Amer. Florist, 10 (1895), pp. 930–932*).—An address delivered before the New York Florists' Club, April 8, 1895.

Remarks concerning the necessary amount of light for plants, J. WIESNER (*Ber. deut. bot. Ges., 12 (1894), Generalversammlungs number, 1895, Feb. 12, pp. 78–89*).

The effect of diastatic ferments on reserve cellulose, J. GRUSS (*Ber. deut. bot. Ges., 12 (1894), Generalversammlungs number, 1895, Feb. 12, pp. 60–72*).

The existence and localization of emulsin in Manihot spp., L. GUIGNARD (*Bul. Soc. Bot. France, 41 (1894), pp. CIII–CVII*).

On the presence of essence of wintergreen in various plants, E. BOURQUELOT (*Bul. Soc. Bot. France, 41 (1894), pp. XXXVII–XL*).—In addition to species of *Gaultheria* and *Betula* it is reported as found in *Polygala* spp. and *Monotropa hypopytis*.

On the distribution of phosphorus in plants, G. POLLACCI (*Malpighia, 4, No. 8 and 9, p. 19; abs. in Bot. Centbl., 61 (1895), No. 11, pp. 399, 400*).

On the classification of mucilage found in plants, L. MANGIN (*Bul. Soc. Bot. France, 41 (1894), pp. XL–XLIX*).—The various kinds of mucilage are classified according to their action toward certain chemicals, into cellulose, pectose, callous, mixed and intermediate.

The reasons for the disappearance of reserve material in seeds (*Flora, 79 (1894), pp. 419–429; abs. in Bot. Centbl. Beihefte, 5 (1895), No. 1, p. 23*).

The nutrition of green plants by glycerin, E. ASSFOHL (*Jour. Pharm. et Chim., 14 (1894), ser. 5, No. 12, p. 558; Ann. Agron., 1894, Oct. 28*).

Phenological notes on abnormal inflorescence observed in the autumn of 1893, A. MAGNIN (*Ann. Soc. Bot. Lyons, 19 (1894)*).

Concerning the symbiosis of Helianthus tuberosus and H. annuus induced by grafting, H. VÖCHTING (*Sitzungsber. kgl. Akad. wissensch. Math. phys. Classe, 1894, July 12; abs. Bot. Ztg., 53 (1895), II, No. 7, pp. 112–115*).

A room for constant temperature, W. PFEFFER (*Ber. deut. bot. Ges., 13 (1895), No. 2, pp. 49–54, fig. 1*).—A description of an apparatus for regulating the temperature of a room.

Investigations on nuclear division, DEGAGNY (*Bul. Soc. Bot. France, 41 (1894), No. 8 and 9, pp. 588–596*).

The effect of the repression of certain bacteria through the continued cultivation of legumes, A. HILL (*Ztschr. landw. Ver. Hessen, 1895, No. 11, pp. 81, 82*).—The author claims that the continued cropping of legumes will fill the soil with only those bacteria concerned in the assimilation of free nitrogen to the entire displacement of all neutral forms.

Experimental evolution amongst plants, L. H. BAILEY (*Amer. Nat., 29 (1895), pp. 318-325*).—An abstract of an address before the Massachusetts Horticultural Society, February 23, 1895.

Flowers and insects, XIV, C. ROBERTSON (*Bot. Gaz., 20 (1895), No. 4, pp. 139-149*).—A continuation of the observations of the author on the mutual adaptations of flowers and their insect visitors, with lists of insects observed to visit certain flowers.

Guide to the study of common plants, an introduction to botany, V. M. SPALDING (*Boston: D. C. Heath & Co., pp. 294*).

METEOROLOGY.

The needs of meteorology, C. ABBE (*Science, 1895, Feb. 15, pp. 181, 182*).—Considered as a source of climatological statistics and as a system for the prediction of the weather for a day or two in advance, meteorology has received enthusiastic support. About all that can be done by the utilization of the telegraph and weather map and the application of general average rules is now being done; but we are still powerless in the presence of any unusual movement of the atmosphere. Meteorologists must have a deeper insight into the mechanics of the atmosphere. It is not enough to know what the conditions have been and are, but we must know what they will be and why. A complete and rigorous deductive treatise on the laws governing the atmosphere is needed—a treatise on the application to the atmosphere of the dynamics and thermodynamics of gases and vapors. The preparation of such a work demands appropriate laboratory arrangements. Hence the great need of meteorology at present is the establishment of laboratories and the consecration of physicists and mathematicians to the science. The applications of climatology to geology, physiography, hygiene, irrigation, and other matters have been developed, but meteorology itself still remains to be provided for. Our universities should recognize the science to a greater extent in their courses of study and provide for meteorological laboratories.—O. L. FASSIG.

Rainfall and snow of the United States compiled to the end of 1891, M. W. HARRINGTON (*U. S. Dept. Agr., Weather Bureau Bul. C, pp. 80, fig. 1, charts 23*).—Tables give the annual precipitation in the United States (1738 to 1891); annual and seasonal averages, seasonal variation, and cubic miles for each State; mean daily rainfall for 18 to 28 years at 12 selected stations expressed as a percentage of days on which rain fell; combined averages of hourly occurrences of precipitation at Blue Hill Observatory, near Boston, Massachusetts, Washington, D. C., and Central Park, New York, New York; details of precipitation, and heaviest rainfalls at selected representative stations. Colored charts (published separately) show rainfall (January to December), rainfall for seasons, rainfall for the year, snowfall (in inches), monthly maxima of rainfall, rainy seasons, monthly minima of rainfall, details of rainfall, and details of occurrence of thunderstorms. The text discusses, under the head of mean amounts of rainfall, least rainfall, greatest rainfall, topography and its effects on rainfall, snow, distribution by States, disposal of the rainfall, variation in the annual rainfall, daily rainfall, and hourly rainfall; under relative amounts of precipitation, curves, maximum monthly rainfall, rainy seasons, minimum monthly rainfall, probability of rain, and character of rainfall; under special features of rainfall, heaviest rainfall, consecutive days with and without rain, and thunderstorms.

"The statistics of rain and snow, here given, include the most important series of observations that have been made from the early settlement of the country to the close of the year 1891.

"The collection embraces the records originally contributed to the Smithsonian Institution in manuscript, and others collected by that Institution from private individuals, those from the published journals of scientific societies and other associations, those made under the direction of the Medical Department of the U. S. Army, the Lake Survey, the Regents of the University of the State of New York, the Central and Southern Pacific Railways, the various State Weather Services and meteorological associations, the Signal Service, and, finally, the Weather Bureau, which succeeded it."

Depth of snow on ground during February, 1895 (*U. S. Dept. Agr., Weather Bureau, Weekly Snow Charts for Feb., 1895*).—The charts for February show a very unusual extent of snow-covered ground during the greater part of the month. February 11 the entire country, with the exception of the southern portions of the Gulf States and the Pacific Coast, had a depth varying from 1 in. in the South to 15 in. in the Northwest and Northeast, and 35 in. in upper Michigan. By February 28 it had practically disappeared from all portions of the United States excepting the lake regions and the extreme Northeast.

The chart for Feb. 11 contains an interesting note relating to the cold period of Feb. 1 to 11.

"At a majority of stations over the central and southern portions of the country the minimum records for the first decade of February have been lowered. At Galveston and New Orleans, where the records cover nearly a quarter of a century, the minimum temperature of February 8 reached 14° and 16°, respectively, that at Galveston being 14° below any previous record of the first decade of February, the record at New Orleans being lowered by 9°."—O. L. FASSIG.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 22 (1894), Nos. 9–11, pp. 351–485, charts 19*).—These numbers include the usual notes and summaries. Beginning with the September number a new section on "Meteorology and magnetism" is introduced.

"In response to the request of the chief of the Weather Bureau, the directors of the observatories at Toronto, Washington, and San Antonio have courteously undertaken to forward to the Bureau, as promptly as possible, certain data from their magnetograms, namely, the mean ordinates for the day from 24 hourly readings of the horizontal force, the declination, and the vertical force, uncorrected for instrumental errors and changes of temperature. On days exhibiting very disturbed magnetic conditions the hours and the values of the maximum and minimum ordinates are given.

"The object in collecting these data is to institute a comparison between the crude magnetic readings, particularly of the bifilar, and the temperature changes at meteorological stations in the Northwest. Ultimately such comparisons will show how far unreduced magnetic observations may be available for determining the direction and the intensity of the temperature variations and other weather conditions before these become fully developed, as given by the isotherms and isobars of the daily weather maps. It has already been shown that weather and magnetism conform on the average to a normal type, but the problem of the synchronous changes from day to day is still under advisement as a practical feature in forecasting."

Wreck and casualty chart of the Great Lakes, 1894 (*U. S. Dept. Agr., Weather Bureau, 1 chart with text, 25 by 36 in., Feb., 1895*).—This chart gives in detail the number of casualties occurring on Lakes Superior, Michigan, Huron, Erie, and Ontario, and the connecting rivers during the season of 1894, and includes besides the record of total loss of 44 vessels and cargoes, involving a loss of $643,243, the partial loss of 68 vessels and cargoes to the amount of $349,544, and the sacrifice of 68 lives.—O. L. FASSIG.

Meteorology in France during 1892, E. MASCART (*Ann. Bureau Central Météorol. France, 1892, 3 vols. Paris: 1894*).—The following memoirs occur annually in volume I of this series: Summary of thunderstorms in France; magnetic observations made at the observatory of Parc Saint-Maur; magnetic observations made at the observatory of Perpignan; magnetic determinations made in France; study of the progress of the phenomena of vegetation and the migration of birds; meteorological observations made at the Central Meteorological Bureau and upon the Eiffel Tower. Besides the above annual reports the volume contains: First series of meteorological observations made on Mont Blanc in 1887, by J. Vallot; remarks upon the observations made on the summit of Mont Blanc in 1887, by A. Angot; summary of studies of the progress of phenomena of vegetation and the migration of birds in France during the 10 years 1881–'90, by A. Angot; squalls and thunderstorms, by E. Durant-Gréville.

Volume II contains the observations made during the year at 126 stations in France, 36 stations in Algeria, and at 23 colonial stations. Volume III contains a detailed statement of rainfall at 409 stations in France.—O. L. FASSIG.

Rainfall of the Hawaiian Islands, J. HANN (*Meteorol. Ztschr., Wien (1895), pp. 1–14*).—The islands lie in the heart of the northeast trades. According to McKibben, the trades prevail during 258 days at Honolulu. This insures a constant temperature, but great variation in rainfall in the mountainous regions.

The greatest precipitation occurs on the windward side of the southeasterly and largest of the islands, Hawaii, which has a maximum fall of about 600 cm. (240 in.). The minimum fall occurs on the southern plains of Oahu and along the southwest coast of Maui, reaching scarcely 40 cm. (16 in.).

Rainfall at Honolulu.

Meteorological observations at Upsala, Sweden, 1894, H. H. HILDEBRANDSSON (*Bul. mensuel Observ. Météorol. Univ. Upsala, 26 (1894), pp. 74*).—The records for pressure, temperature, humidity, direction, and velocity of wind are given in hourly values.

The mean temperature for the year was 6° C.; mean maximum, 10.2°; mean minimum, 1.6°; humidity, 81; cloudiness, 6.1; and rainfall, 486.5 mm.—O. L. FASSIG.

Meteorological observations at Porto Rico, 1894 (*Resumen observ. meteorol. verif. Jefatura de Obras Públicas Isla Puerto-Rico, 1894*).—The summary for the year is as follows: Maximum temperature at the surface of the ground, 36° C.; maximum temperature in the shade, 33.2°; mean temperature in the shade, 23.1°; minimum temperature, 14°; total rainfall, 1,227.7 mm.; maximum rainfall in one day, 53 mm.; total evaporation, 2,357.7 mm.; maximum evaporation in one day, 15 mm.; order of frequency of the wind, E., SE., NE., S., NW., N., W., SW. The mean shade temperature for 15 years was 23.9° C.; mean rainfall for 20 years, 921.8 mm.; mean evaporation for 20 years, 2,501.5 mm.; order of frequency of winds during 20 years, E., NE., SE., N., S., NW., SW., W.—O. L. FASSIG.

On hail, R. RUSSELL (*London: 1893, pp. 224, pls. 2*).—This is a valuable compilation of statistics relating to hailstorms and hailstones. The contents of the book are well indicated by the chapter headings: (1) Descriptions of hailstorms and hailstones; (2) observations of temperature, clouds, and winds at great altitudes (balloon ascents); (3) electricity and hail; (4) theories of hail; (5) certain properties of vapor, water, ice, and conditions of the air which may be connected with the formation of hail; (6) summary of characteristics of hailstorms and hailstones; (7) the development of a hailstorm; (8) conclusions.

Appendixes: (A) General weather conditions in certain hailstorms, (B) cold produced by radiation from the upper strata of clouds and fog, (C) dust particles and the form of ice crystals, (D) types of hailstorms, (E) notes on recent thunderstorms and hailstorms, (F) storms of hail and rain produced by mixture of winds.—O. L. FASSIG.

Recent foreign studies of thunderstorms, R. DEC. WARD (*Amer. Met. Jour., 11 (1895), No. 12, pp. 435–441*).—A review of investigations in this line in Switzerland.

The influence of the snow covering on soil and climate, M. WINTER (*Landw. Wochenbl. Schles. Holst., 45 (1895), No. 7, pp. 108, 109*).

Daily weather maps.—The countries which issued weather maps during 1894, the area covered by each (in parenthesis), and the years of publication are: Austria (Europe), eighteenth year of publication; Algeria (Europe and northern Africa), nineteenth year of publication; Belgium (southern, western, and northern Europe), eighteenth year of publication; France (Europe), thirty-eighth year of publication; Germany—Hamburg (Europe), nineteenth year of publication; Germany—Bavaria (Europe), fourteenth year of publication; Germany—Saxony (Europe), seventeenth year of publication; Great Britain (British Isles and western Europe), twenty-seventh year of publication; India (India and Burma), sixteenth year of publication; Italy (southern Europe), sixteenth year of publication; Japan (Japan), twelfth year of publication; Russia (Europe), twenty-third year of publication; Spain (Spain, France, and northern Italy), second year of publication; United States (United States and southern Canada), twenty-fourth year of publication; Switzerland (Europe), fourteenth year of publication.

Most of these maps have been received in the library of the Weather Bureau of this Department.—O. L. FASSIG.

Weather record at Newport (Arkansas) Substation for the season of 1894, G. B. IRBY (*Arkansas Sta. Bul. 31, p. 32*).—A daily record of maximum and minimum temperatures and rainfall for 7 months (April to October).

Meteorological summaries for North Carolina for December, 1894, H. B. Battle, C. F. von Herrmann, and R. Nunn (*North Carolina Sta. Weather Service Bul. 63, pp. 187–200, maps 2*).—The usual summaries of observations of the State Weather Service coöperating with the Weather Bureau of this Department.

Notes on climate of Wyoming, B. C. Buffum (*Wyoming Sta. Rpt. 1894, pp. 36–45*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 18).

Observations of the New England Weather Service, 1893 (*Annals of Harvard Coll. Observatory, vol. 41, No. 2, pp. 33–61, pl. 1*).—The usual annual summary of observations from about 200 stations, with general characteristics of the weather, and enumeration of the principal cyclonic disturbances during the year. The following departures from annual normal values during the period 1885–'93 are given:

Departures from annual normals, 1885–'93.

	1885.	1886.	1887.	1888.	1889.	1890.	1891.	1892.	1893.
From the temperature normal (degrees)	−1.3	−0.40	−0.50	−1.80	+1.70	+0.10	+1.4	+0.20	−1.40
From the precipitation normal (in.)	−1.2	+0.93	+2.69	+11.76	+4.25	+4.59	+0.2	−0.48	−0.29

—O. L. FASSIG.

Weather and crops, C. E. Linney (*Illinois State Weather Service (1895), No. 1, pp. 8*).—The central office of the Illinois State Weather Service was recently transferred from Springfield to Chicago, with W. L. Moore in charge. "Weather and Crops" is the title of the official monthly publication of this service. It is a very creditable addition to the numerous State Weather Service monthly reviews.—O. L. FASSIG.

Weather Service in Pennsylvania.—In a communication to the senate and house of representatives of the State of Pennsylvania from the Franklin Institute (6 octavo pages) the value of a State Weather Service is set forth and an appropriation of $6,000 for maintaining such a service is urged.—O. L. FASSIG.

Temperature and rainfall charts for the Dominion of Canada, January, 1895.—The Central Meteorological Office at Toronto has begun the issue of monthly charts, of which this seems to be the first, showing the mean temperature and the difference from the mean average temperature, the total rainfall and snowfall, and the depth of the snow on the ground on the last day of the month. The size of the map is about 24 by 11 in. The region covered is a narrow belt of about 4 degrees, extending from the Atlantic to the Pacific.—O. L. FASSIG.

Central American rainfall, M. W. Harrington (*Phil. Soc. Washington, Bul. 13 (1895), pp. 30, pls. 4*).—This paper deals with the nature and extent of observations recorded; geographic conditions; annual rainfall; distribution during the year; distribution through the day at San José, Costa Rica; and variation of rainfall.

Snow charts of Austria, winter of 1894–'95 (*K. K. Österr. Central Bureau hydrog. Dienst, Wien*).—Charts showing depth of snow on the ground on Saturday of each week in the drainage area of the Danube, with tabular review.—O. L. FASSIG.

Meteorological observations in Würtemberg in 1893 (*Deut. Met. Jahrbuch, 1893, pp. 69, pls. 2*).—This volume contains the records from 100 stations for observing meteorological and phenological phenomena. The establishment of a station of the first order at Hohenheim is described by Prof. Dr. Mack, who also discusses the daily periods of rainfall from observations covering a period of 10 years at this station.—O. L. FASSIG.

Indian meteorological memoirs (*Volume V, parts IV, V, and VI. Calcutta: 1894*).—Volume V treats of the diurnal variation of atmospheric conditions in India, being a discussion of the hourly observations recorded at 25 stations since 1873. Part IV discusses the hourly observations at Allahabad; part V, the observations at Lucknow; part VI, the observations at Agra.—O. L. FASSIG.

Instructions to observers of the India Meteorological Department, J. ELIOT (*Calcutta: 1894, pp. 103, pls. 3*).—This pamphlet of "instructions" is intended to supersede the well-known and excellent "Indian Meteorologist's Vade Mecum" published in 1877, but is much reduced in size and scope. It is confined to a description of the various instruments in use at the meteorological observatories in India, as all reductions of observations are made at the Meteorological Office, Calcutta.—O. L. FASSIG.

Meteorological observations in Italy, 1890 (*Ann. Uff. Cent. Meteorol. Geod. Ital., 12 (1890), II. Roma: 1895, pp. 383*).—Part II of the Annali contains the decade, monthly, and annual means for all stations in Italy under the direction of the national central office. In addition to the ordinary observations the amounts of evaporation are given for 63 stations for each decade.—O. L. FASSIG.

Meteorological observations in Mexico, 1894 (*Obs. Met. Magnét. Central., 1894, Dec. Mexico: pp. 9*).—Summaries for December, with annual means.

Russian Monthly Weather Review, Jan.-Dec., 1894 (*St. Petersburg: 1894*).—The reviews contain the ordinary meteorological observations for about 75 stations in the Russian Empire. Each number comprises 10 large quarto pages of tabular matter, and text (in the Russian language), together with a chart showing the mean monthly pressure and temperature and total rainfall.—O. L. FASSIG.

Meteorological observations in Sweden during 1890 (*Acad. Roy. Sci. Sweden, 32 (1890). Stockholm: 1894, pp. 155*).—The volume is divided into 3 sections. The first contains observations *in extenso* at 18 stations, the second the monthly and annual means of all meteorological elements for 37 stations and of temperature for 93 stations, and the third pentad means for the 37 stations of part 2.—O. L. FASSIG.

WATER—SOILS.

Further investigations on the soils of Maryland, M. WHITNEY and S. KEY (*Maryland Sta. Bul. 29, pp. 153–174*).—A brief discussion of "some of the underlying principles of the relation of soils to crops" more fully treated in the Annual Report of the station for 1891 (E. S. R., 4, p. 17) and Bulletin 21 of the station (E. S. R., 5, p. 162), with a report on physical examinations of typical truck and wheat soils of the Eastern Shore of Maryland; limestone soils of the Cumberland and Frederick Valleys; mountain peach soils (Cambrian sandstone); gneiss soils (corn and wheat) from Bel Air, Darlington, Churchville, and Glenville; and wheat and corn soils of southern Maryland.

Soil temperature observations in Cordova, Argentine Republic (*An. Ofic. Meteorol. Argentina, vol. IX. Buenos Ayres: 1891*).—Observations of temperature in the soil at the surface and at depths of 0.1, 0.25, 0.5, 1.2, 2.7, and 3.75 meters are reported. A summary of results for the year is given in the following table:

Soil temperatures (degrees C).

	At surface	0.1 meter	0.25 meter	0.5 meter	1.2 meters	2.7 meters	3.75 meters.
Maximum	29.4	25.6	24.2	22.8	21.5	22.0	20.2
Minimum	2.9	5.3	6.8	10.0	13.8	14.9	17.8

—O. L. FASSIG.

Soil temperatures in Bombay, India, 1893 (*Mag. and Met. Observ., Government Observatory, Bombay, 15 (1894), No. 15, pp. 12*).—Soil temperatures are reported for depths of 1, 9, 20, 60, and 132 in. below the surface, the 2 former 5 times daily, the 3 latter once a day at 2 p. m. The maximum and minimum readings were as follows:

Soil temperatures (degrees F.).

	1 inch.	9 inches.	20 inches.	60 inches.	132 inches.
Maximum	85.6 (May)	84.9 (May)	85.8 (June)	85.6 (June)	84.0 (July).
Minimum	74.8 (Feb.)	75.0 (Feb.)	78.0 (Feb.)	80.9 (Feb.)	81.2 (March).

—O. L. FASSIG.

Analyses of drinking water, J. L. HILLS and B. O. WHITE (*Vermont Sta. Rpt. 1893, pp. 22–25*).—Analyses with reference to sanitary condition of 25 samples of spring water, 17 of well water, 7 of pond and aqueduct water, and 10 of Lake Champlain water are tabulated.

Soil temperatures, B. C. BUFFUM (*Wyoming Sta. Rpt. 1894, p. 42*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 23).

Investigations on the radiation of heat by the soil, J. AHR (*Forsch. Geb. agr. Phys., 17 (1894), No. 5, p. 397*).

Exhaustion of soil by trees (*Garden and Forest, 8 (1895), pp. 142, 143*).—Quotes a letter from B. E. Fernow on the subject.

The reclamation of arid lands, A. A. JOHNSON (*Wyoming Sta. Rpt. 1894, pp. 47–65*).—A reprint from Bulletin 18 of the station (E. S. R., 6, p. 345).

FERTILIZERS.

The world's consumption of fertilizers—nitrate of soda, MAZIÈRES (*L'Engrais, 10 (1895), Nos. 13, pp. 299, 300; 14, pp. 324, 325*).—The amount and value of nitrate of soda consumed in different countries is stated to be as shown in the following table:

Consumption of nitrate of soda in different countries.

	Amount consumed.					Value in 1894.[1]
	1890.	1891.	1892.	1893.	1894.	
	Tons.	*Tons.*	*Tons.*	*Tons.*	*Tons.*	
Germany	316,300	368,400	366,800	349,000	397,200	$15,848,280
France	197,900	183,400	175,400	175,700	187,100	7,465,290
England	119,000	124,400	118,800	101,800	117,000	4,668,300
Belgium	91,600	94,600	95,100	100,000	123,700	4,835,630
Holland	47,200	48,500	47,400	53,700	56,700	2,262,330
Italy and Spain	13,800	9,300	8,500	9,000	5,200	207,480
America	103,000	100,000	100,000	104,000	100,000	3,990,000

[1] The value per ton is taken as 210 francs, or $39.90. The French ton contains 2,204.6 lbs.

The influence of the mineralogical composition of rocks on vegetation, F. X. GILLOT (*Bul. Soc. Bot. France, 41 (1894), pp. XVI–XXXVI*).—Investigations are reported which led to the following conclusions: The appearance of certain species of plants usually associated in soil apparently different from that of its ordinary habitat (heteroptic colonies) depends not only on the presence of sufficient chemical elements in the soil, but also on the combinations and proportion of these elements in the soil and in the minerals from which they are derived, and on the power which the plants possess of utilizing these fertilizing elements.

Recent investigations on the nitric ferment, VOGEL (*Jahrb. deut. Landw. Ges., 9 (1894), pp. 28-30*).—A brief review of the work of Winogradsky, Stutzer, Rubner, A. Müller, and Tacke.

Bones, their manufacture in fertilizers and value in agriculture, BRAUER (*Jahrb. deut. Landw. Ges., 9 (1894), pp. 30-34*).—A popular article.

The utilization of the nitrogen in green manures and in stable manure, J. KÜHN (*Landbote, 16 (1895), No. 18, pp. 155-157; No. 19, pp. 166-169*).—See E. S. R., 6, p. 396.

Gulick's mineral fertilizer, P. COLLIER (*Cult. and Country Gent., 1895, Apr. 4, p. 264*).

Genuineness of basic slag, F. SESTINI (*Staz. Sper. Agr. Ital., 26 (1894), pp. 57-62; abs. in Jour. Chem. Soc. London, 68 (1895), Mar., p. 86*).

The phosphate deposits of North America, WOHLTMANN (*Jahrb. deut. Landw. Ges., 9 (1894), pp. 101-119*).—A brief discussion of character and extent of deposits, composition, market price, and exports of Canada, South Carolina, and Florida phosphates, with remarks on their importance to German agriculture.

Fertilizer experiments of the German Agricultural Society, C. NÖRMER (*Landw. Wochenbl. Schles. Holst., 45 (1895), No. 8, pp. 127, 128*).

Tables for calculating fertilizer analyses, H. B. MCDONNELL ET AL (*Maryland Sta. Bul. 29, Appendix, pp. 16*).—Tables show (1) side by side the per cent of phosphoric acid and tri-calcium phosphate corresponding to the weight of magnesium pyrophosphate calculated for 0.4 gm. substance; (2) phosphoric acid corresponding to weight of magnesium pyrophosphate calculated for 0.4 and 0.5 gm. substance and for each tenth of a milligram; (3) potash, K_2O, corresponding to weight of $KPtCl_6$ calculated for each milligram and for 1 gm. substance; (4) per cent of nitrogen corresponding to each tenth cubic centimeter of one tenth normal solution; (5) per cent of ammonia, NH_3, corresponding to each tenth cubic centimeter of one tenth normal solution; and (6) the value per ton of fertilizers from percentage for prices of 6, 3, and 2 cts. per pound.

Fertilizer analyses of the North Carolina Fertilizer Control, H. B. BATTLE (*North Carolina Sta. Special Buls. 22, pp. 10; 23, pp. 12*).—Tabulated analyses of samples of fertilizers accompanied by the usual explanatory notes.

Fertilizer inspection in Rhode Island, H. J. WHEELER and B. L. HARTWELL (*Rhode Island Sta. Bul. 30, pp. 59-65*).—Tabulated analyses and valuations of 27 samples of fertilizers; a table giving statistics of fertilizer inspection during 1894 and agreement of actual and guaranteed composition; and notes on valuation.

Report of analyses of fertilizers and feeding stuffs made under the act of 1893 (*Jour. [British] Board. Agr., 1 (1895), No. 3, pp. 276, 277*).—Four hundred and forty-four samples were analyzed during 1894, 317 being of fertilizers and 127 of feeding stuffs.

Analyses of fertilizing materials, J. L. HILLS and B. O. WHITE (*Vermont Sta. Rpt. 1893, pp. 21, 22*).—Analyses of 19 samples of wood ashes, 3 of muck, 1 of tankage, and 2 of a mixed fertilizer are tabulated.

Analyses of fertilizers licensed for sale in the State of Vermont in the year 1893, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 17-19*).—An abstract of Bulletin 35 of the station (E. S. R., 5, p. 164).

FIELD CROPS.

Alfalfa, how and where to grow it, C. W. IRISH (*pp. 11*).—This pamphlet gives directions for the choice and preparation of the soil, for sowing the seed, and for the management of the crop in semiarid regions, both with and without irrigation. The author states that the seed furnishes a valuable dyestuff and that for this use large quantities of seed are exported from this country to France. Several examples illustrating the depth to which alfalfa roots penetrate, and several instances of a successful catch of alfalfa secured without irrigation on light, sage brush land, by simply harrowing the surface without plowing, are given. On mountain slopes in Nevada it is claimed that the plant withstands extremely low temperatures. Young frosted shoots may induce bloating in animals, as will overfeeding with green alfalfa.

Fertilizer experiments with buckwheat, J. C. CHAPMAN (*Southern Planter, 56 (1895), No. 3, pp. 112, 113*).—This experiment was conducted on a well-worn clay loam soil near Fredericksburg, Virginia. The seed was sown July 25 at the rate of 15 qts. per acre. On account of drought the stand was very thin and the yield was very small. Neither gypsum, air-slacked lime, nor muriate of potash alone increased the yield over that of the unfertilized plats. Indeed, muriate of potash when applied at the rate of 100 lbs. per acre either alone or in combination appeared to reduce the yield. Nitrate of soda and superphosphate applied alone and in combination increased the yield. A complete fertilizer consisting of 120 lbs. of nitrate of soda, 340 lbs. of superphosphate, and 50 lbs. of muriate of potash gave the largest yield.

Analysis of burnet (Poterium sanguisorba), J. HENDRICK (*Rpt. Expts. Manuring, 1893, Glasgow and West Scotland Tech. Col. Glasgow: 1894, pp. 28, 29*).—The dry matter of burnet, cut just as the plant was coming into bloom, had the following composition:

	Per cent.
Nitrogenous matter	25.50
Fat	4.14
Nitrogen-free extract	53.18
Fiber	10.28
Ash	6.90
	100.00

The percentage of total nitrogen in the dry matter was 4.08, and of albuminoid nitrogen 2.78.

Serradella was also analyzed, and the dry matter afforded 3.54 per cent of total nitrogen and 2.01 per cent of albuminoid nitrogen.

Experiments with corn, R. J. REDDING (*Georgia Sta. Bul. 27, pp. 187–195*).

Synopsis.—Tests of fertilizers, of cotton-seed meal and cotton hulls applied together *vs.* cotton seed, variety tests, and an experiment in pulling fodder. All of the fertilizer mixtures caused a financial loss. Cotton-seed meal and hulls proved slightly superior to cotton seed. Fodder pulling yielded a slight net profit, although it reduced the yield by 2.77 bu. of corn per acre.

These experiments are in continuation of those reported in Bulletin 23 of the station (E. S. R., 6, p. 223). The weather conditions for the season are noted, the rainfall being tabulated.

Fertilizer experiments (pp. 188–190).—The basal mixture consisted of 312 lbs. of acid phosphate, 18 lbs. of muriate of potash, and 130 lbs. of nitrate of soda per acre, and cost $6. Every increase in one or more of the ingredients caused a financial loss, as did the basal mixture itself. The conclusions agree with those of previous years that it is not expedient to rely on commercial fertilizers for corn, but that this crop should follow a well-fertilized cotton crop. Nitrogen was the most effective of the 3 fertilizer constituents used.

Cotton-seed meal and hulls vs. cotton seed (pp. 194, 195).—Seven hundred and sixty-four pounds per acre of crushed cotton seed yielded 0.86 bu. of corn less than did the meal and the hulls obtained from the above amount of cotton seed, the quantities of minerals applied being the same with each.

Varieties (pp. 192, 193).—Of 13 varieties tested the largest yield (13.19 bu. per acre) was made by Shaw Improved.

Pulling fodder (pp. 190–192).—Pulling fodder (stripping the blades) reduced the yield of corn 2.77 bu. per acre. The yield of blades was 587 lbs. per acre on fertile land. With corn at 65 cts. per bushel and fodder at 75 cts. per 100 lbs., pulling fodder resulted in a net gain of 92 cts. per acre.

Varieties of corn, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 111–114*).—Tabulated data give the characteristics and composition of 13 varieties of corn. The largest yield of dry matter was made by Virginia Horse Tooth, Leaming, and Egyptian Sweet. The dry matter of the Egyptian Sweet corn had a larger nutritive value, pound for pound, than that produced from any other variety.

Field experiments with cotton, R. J. REDDING (*Georgia Sta. Bul. 27, pp. 196–210*).

Synopsis.—These consisted of (1) variety tests, in which Jones Improved gave the largest value of lint and seed; (2) distance experiments, in which the results favored a distance of 1 by 4 ft.; (3) fertilizer experiments; (4) an experiment in plowing under green pea vines, mature pea vines from which the peas had been picked, and pea vine stubble, resulting in favor of making hay of the vines and plowing under the stubble; and (5) a test of Florida phosphate *vs.* superphosphate, resulting in favor of the latter.

These experiments are in continuation of those reported in Bulletin 23 of the station (E. S. R., 6, p. 527).

Test of varieties (pp. 196–200).—Fifteen varieties were tested. The yield at each picking, number of bolls to a pound of seed cotton, number of seeds in 1 lb., yield of lint and seed, per cent of lint, and total value of lint and seed are tabulated. The largest yield of lint (628 lbs. per acre) and also of seed was made by Jones Improved; this variety stood second in size of boll and fourth in earliness.

The small seeded varieties "are better suited to thin or moderately fertilized soils, since they make smaller drafts on the soil; while the larger bolled, larger seeded varieties are perhaps better adapted for high culture, for strong or liberally manured soils."

Distance experiments (pp. 200–202).—In rows 4 ft. apart single stalks were left at distances of 1, 2, 3, and 4 ft. Both on the plats liberally fertilized and on the unfertilized plats the largest yield was made at distances of 1 by 4 feet. The following table gives the yields of seed cotton at each of these distances for each of the years during which the experiment has been in progress:

Yield of seed cotton at different distances.

	4 by 1 ft.	4 by 2 ft.	4 by 3 ft.	4 by 4 ft.
1891	1, 943	2 027	2, 007	1, 883
1892	1, 616	1, 516	1, 501	1, 430
1893	1, 903	1, 905	1, 925	1, 770
1894	2, 065	1, 812	1, 843	1, 671
Averages of 4 years	1, 882	1, 815	1, 819	1, 678

The author advises early planting when it is intended to give each stalk ample distance, and close planting as the northern limit of the cotton belt is approached.

Effect of increasing amount of fertilizer (pp. 202–204).—In this experiment a complete fertilizer was applied at the rate of 400, 800, and 1,200 lbs. per acre, and the results were compared with those secured on unfertilized plats. With the variety King the use of 400 lbs. of fertilizer resulted in a profit of 71 per cent on the investment for fertilizers; for the variety Jones Improved, 14 per cent. Using 800 lbs. of fertilizer there was a profit of 11 per cent with King, but a loss of 8 per cent with Jones Improved. Twelve hundred pounds of fertilizer resulted in a financial loss with both varieties.

General fertilizer experiments (pp. 205–207).—In 1894 the formula giving best results consisted of 468 lbs. of acid phosphate, 54.6 lbs. of muriate of potash, and 130 lbs. of nitrate of soda, and the mixture contained 10 per cent available phosphoric acid, 4 per cent potash, and 3 per cent nitrogen. With none of the fertilizer mixtures was there any considerable profit.

Green manuring with cowpeas (pp. 207–209).—Cowpeas planted after oats in 1893 were plowed under (1) green, or (2) after the peas had been picked, or (3) the stubble was plowed under, the vines being made into hay. The results agree with those of previous years in showing that the greatest profit (taking into consideration the value of the cotton crop of 1894 and the value of the cowpeas and hay in 1893) was obtained by making hay of the vines and plowing under the stubble.

Florida soft phosphate vs. superphosphate (pp. 209, 210).—Superphosphate in a complete fertilizer was compared with an equal amount and with larger amounts of Florida soft phosphate. Superphosphate at $14 per ton proved far superior both in yield and in financial returns to soft phosphate at $12 per ton.

Miscellaneous fodder crops, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 114–118*).—The composition and yield per acre of food constituents are tabulated for Japanese radish, spurry, millet, rape, soja bean, horse bean, and sunflowers, and for mixtures of peas, oats, and rape, hairy vetch and soja beans, hairy vetch and horse beans, and vetch, oats, and rape. The largest yield of dry matter, 7,491 lbs. per acre, was made by rape; this plant produced a larger crop when the drills were 6 in. apart than when planted at a distance of 27 in. apart. Japanese radish was refused by cattle; sunflower heads afforded 2,738 lbs. dry matter per acre, containing 607 lbs. of fat, a much larger quantity than that produced by any other crop.

American ginseng, G. V. NASH (*U. S. Dept. Agr., Division of Botany Bul. 16, pp. 22, figs. 2*).—The roots of ginseng (*Panex quinquefolium*) are exported to China, where they are used medicinally. The following topics are treated: History, description, geographical distribution, medicinal properties, commercial value, export statistics, protection against extermination, cultivation, composition, and preparation of ginseng for market.

> "There are two ways in which a start may be made in the cultivation of ginseng, viz, by transplanting the wild roots and by sowing seed. By the latter method from 4 to 7 years are required to produce the first crop of marketable roots, and the land yields no income in the meanwhile. The more speedy and better plan is to transplant wild roots of different ages. This is to be done in the fall of the year, the seed of the plants being collected at the same time and sown . . . The following autumn dig up the roots and replant all that are not of marketable size, sowing all the seed yielded by the bed."

A ginseng bed should be shaded, and hence its best location is in a wood from which the underbrush has been removed. It is recommended to plant the seed in drills 2 or 3 in. apart and 1 in. deep at the rate of 1 seed per inch. The seed should be sown as soon as gathered, or if kept for any time it should be packed in moist loam. If allowed to dry it will not germinate. Eighteen months usually elapse between planting and germination. When the plants are 2 or 3 years old they may be again transplanted to carefully prepared beds.

> "When the plants are from 4 to 7 years old, they are to be dug up in the fall, after the seed is gathered. They should then be sorted, all that are large enough for the market being taken out and the remainder replanted. In digging the roots great care should be exercised not to mutilate them, as their value is increased in proportion to their freedom from blemishes."

The consumption of ginseng is limited and there is a possibility of glutting the market. On the other hand, its culture requires but little capital, and when the price is low the roots can be left in the ground to await higher prices.

Flax culture, STREHL (*Jahrb. deut. landw. Ges., 9 (1894), pp. 137, 138*).—As the result of 10 years' work the author condemns the use of fresh stable manure on flax. An application of 540 lbs. of kainit and 27 to 54 lbs. of soluble phosphoric acid per acre is recommended. The kainit is applied in the fall, superphosphate before planting in spring. The use of nitrate of soda is not advised, as it may cause the crop to lodge.

Preparation of the soil, as thorough as for beets, is advised. Plowing so deep as to bring to the surface some raw soil is not regarded as injurious. A shallow seed bed is made and the seed is sown as early in the spring as practicable. Directions for harvesting and marketing flax and an estimate of the cost of flax production are given.

Flat pea, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Botany Circular 4, pp. 7, figs. 2*).—The subjects treated are description, history, uses, cultivation, and rate of growth of the flat pea (*Lathyrus sylvestris*). The author believes more extensive cultivation is necessary before the true value of this plant can be definitely ascertained. It requires soil in which the water is at least 13 ft. below the surface. Its early growth is slow and it is usually not mowed until the third year.

Effect of fertilizers on lupines, DAMSEAUX (*Jour. Ass. Anc. Élèv. Gembloux, 4 (1894), No. 9, pp. 328–330; abs. in Centbl. agr. Chem., 23 (1894), No. 12, pp. 850, 851*).—The yields of yellow lupines, under the influence of different manures, are given in the following table:

Yield per acre of green material of yellow lupines and nitrogen contained therein.

	Yield per acre.	Nitrogen.
	Pounds.	*Pounds.*
No fertilizer	27,097	136
624 lbs. kainit	28,302	142
490 lbs. quicklime	33,008	166
490 lbs. quicklime 624 lbs. kainit	35,006	176
1,070 lbs. Thomas slag	32,076	160
1,070 lbs. Thomas slag 624 lbs. kainit	32,789	164

The yield was considerably increased where quicklime was used, although the yellow lupine does not prefer a strongly calcareous soil.

The unfertilized plat yielded 7,587 lbs. of fresh roots containing 1,517 lbs. of dry matter. The plat fertilized with lime and kainit, though making above ground a much larger yield of green material than the unfertilized plat, afforded only 5,569 lbs. of fresh roots containing 1,114 lbs. of dry matter.

The plants artificially provided with fertilizing materials produced a smaller amount of roots than those which were compelled to obtain their supply entirely from the soil.

Fertilizer experiments on meadows, R. P. WRIGHT (*Rpt. Expts. Manuring, 1893, Glasgow and West Scotland Tech. Col. Glasgow: 1894,* *pp. 13–26*).—These experiments were conducted in the favorable season of 1893 on 12 farms in the southwestern part of Scotland. In estimating profits only the first cutting or main crop of hay was considered. Were the value of the aftermath included, all fertilizers would show a profit.

Salt was applied early in May at the rate of 768 lbs. per acre, and as no rainfall followed the salt scorched the vegetation. However, the deep-rooted and valuable forage plants on most farms recovered from this injury, while the shallow-rooted weeds, especially the yellow rattle (*Rhinanthus crista-galli*) and *Holcus lanatus*, were to a considerable extent eradicated by the application of salt. This killing of weeds improved the quality of the hay on the plats receiving salt. Salt was more uniformly effective in augmenting the yield of timothy than of mixtures of other grasses and clover.

Nitrate of potash alone, at the rate of 224 lbs. per acre, increased the yield of hay, especially on the plats where there were some clover plants.

Potash in the form of muriate and kainit proved of practically equal value.

Muriate of potash, 224 lbs., and nitrate of soda, 208 lbs. per acre, in combination, largely increased the yield of hay and was profitable. With the addition to this of 312 lbs. of nitrate of potash the yield of hay very largely increased, especially on the timothy plat, the average increase being one fifth of a ton per acre.

Superphosphate gave variable results on different farms and on different species of grasses; on clover its action was especially favorable, but on the average its application to grass was not profitable. Non-nitrogenous mixed minerals proved beneficial on clover, but only slightly effective on grasses. Nitrate of soda alone and in combination resulted in a large and profitable increase in the yield of hay. In every case a complete fertilizer returned a profit.

In a grazing experiment cattle showed a preference for the grasses growing on the plats fertilized with nitrates, either alone or in combination.

Effect of fertilizers on the composition of hay, J. HENDRICK, (*Rpt. Expts. Manuring, 1893, Glasgow and West Scotland Tech. Col. Glasgow: 1894, pp. 27, 28*).—The author's analyses controvert the view sometimes expressed that the hay made from grasses fertilized with nitrates is of inferior nutritive value on account of its large proportion of non-albuminoid nitrogen. The plat receiving a complete fertilizer, in which the nitrogen was in the form of nitrate of soda, yielded hay richer both in total and in albuminoid nitrogen than that from any other fertilized plat.

When potash was applied alone the percentage of total nitrogen was small, but a large proportion of this was in the form of albuminoids.

Fertilizer experiments on oats, R. P. WRIGHT (*Rpt. Expts. Manuring, 1893, Glasgow and West Scotland Tech. Col. Glasgow: 1894, pp. 53–57*).—Commercial fertilizers were in most cases used with profit on the oat crop in the favorable season of 1893. Nitrate of soda applied alone was profitable as a top dressing on soils already in good condition, but on poor land the results were variable. When superphosphate was added to the nitrate of soda the result was more certain and profitable. A complete fertilizer was advantageously used on the oat crop following sod, but potash was not profitable when the preceding crop had been roots liberally fertilized with barnyard manure. Nitrate of soda was somewhat more effective than sulphate of ammonia, especially in the production of straw.

Peanuts, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Bul. 31, pp. 19–23*).—Two varieties grown at the station and at the two substations averaged 73 bu. per acre of selected nuts. The Spanish variety contained in every 100 lbs. of unshelled nuts 79 lbs. of kernels; the Virginia variety only 61 lbs. The Spanish is preferred as a food for hogs. Directions for the cultivation of peanuts are given.

Potatoes, a simple test of quality, E. S. GOFF (*Rural New Yorker, 1895, Apr. 6, p. 241*).—When potatoes are placed for a few minutes in brine the lightest or those of poorest quality and most deficient in starch rise to the top. By this method it is an easy matter with the aid of a hydrometer to determine the amount of starch and hence the quality of the potatoes.

The author planted the light, the medium, and the heavy potatoes as indicated by the brine test for 2 years in succession, and unlike European investigators, noted no improvement in the quality of the crops as a result of this selection. He found that tubers growing nearest the surface were of lowest specific gravity or poorest quality, and that the specific gravity increased with the depth at which the potato grew. This he ascribes to the cooler temperature found at greater depths. He also found that potatoes grown in level culture, with the consequent lower temperature within the soil, had a greater specific gravity than those grown in hills.

Giant knotweed or sachaline, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Botany Circular 5, pp. 4, figs. 3*).—This circular treats of the general characters and history of sachaline (*Polygonum sachalinense*), its probable value as a forage plant and as a protection for river banks, and methods of propagating it. The general cultivation of this plant is not recommended.

Fertilizer experiments on turnips, R. P. WRIGHT (*Rpt. Expts. Manuring, 1893, Glasgow and West of Scotland Tech. Col. Glasgow: 1894, pp. 11, 12, 35–52*).—This experiment was conducted on 16 farms. Large and profitable crops of turnips were grown by the use of mixtures of commercial fertilizers without any farm manures. Phosphoric acid was the most effective fertilizing constituent applied. In the form of superphosphate it was in most cases more valuable than in slag and bone meal. However, on peaty or mossy soils slag was equally effective. Bone meal gave a smaller increase in the yield of turnips than basic slag and nitrate of soda applied together in such quantities as to furnish equivalent amounts of phosphoric acid and nitrogen. Sulphate of potash proved a profitable addition to phosphatic and nitrogenous fertilizers. Barnyard manure alone afforded large crops, but better results were obtained by using half rations (10 tons per acre) of barnyard manure with small quantities of phosphatic and nitrogenous fertilizers.

The soil of the unfertilized plat on one of the farms contained 0.126 per cent of phosphoric acid and 0.116 per cent of potash. The amounts soluble in a 1 per cent solution of citric acid were 0.0054 per cent of phosphoric acid and 0.0062 per cent of potash. This soil responded freely to phosphatic and potash fertilizers, as also to nitrogen. As compared with the unfertilized plat there was an increased yield of 13 tons per acre when a high grade superphosphate was applied, 14 tons when superphosphate and nitrate of soda were used, and 19 tons when superphosphate, nitrate of soda, and sulphate of potash were applied.

Jerusalem artichokes, turnips, and mangel-wurzels, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Bul. 31, pp. 24–28*).—These crops were grown as food for hogs. At Newport Jerusalem artichokes were planted 36 by 18 in. apart and the yield was 453¾ bu. per acre; at Fayetteville the distance was 3 by 3 ft. and the yield 612 bu. per acre. Nineteen varieties of turnips were grown. The test of mangel-wurzels was unsatisfactory. Food analyses of artichokes, sweet potatoes, mangel-wurzels, and turnips are given.

Experiments at Borsbeke-lez-Alost (Belgium), P. DE VUYST (*Rev. Agron. Louvain, 3 (1894), No. 4, pp. 251–286*).—These consisted of fertilizer experiments and variety tests on potatoes, oats, carrots, parsnips, and turnips, and culture experiments with potatoes, maize, and roots.

In experiments with beets, wheat, and potatoes the plats submitted to an electric current produced by a zinc and copper couple afforded smaller yields than the check plats. With potatoes the application of nitrate of soda at planting time and during cultivation gave practically the same results. The continued selection of seed potatoes during 3 years by planting those which had the highest percentage of starch, as shown by their sinking in brine, increased the yield 6.5 per cent and raised the percentage of starch in the crop.

On beets the nitrogen of nitrate of soda was more effective than that of sulphate of ammonia. Nitric nitrogen applied at planting afforded a larger yield than an intercultural application. Kainit was of less value on carrots than on parsnips.

Fertilizer experiments with cereals and potatoes at the Swedish Agricultural College, 1892–'93, S. RHODIN (*Kgl. Landt. Akad.*

Handl. Tidskr., 33 (1894), pp. 297–312, 372–384).—Nitrate of soda vs. fish guano for spring wheat and for oats.—The following are the average yields with the different applications of fertilizers:

Yield of wheat and oats with nitrate of soda and fish guano.

Fertilizer.	Nitrogen per hectare.	Time of application of fertilizers.	Yield per hectare.	
			Grain.	Straw.
Spring wheat.	*Kg.*		*Kg.*	*Kg.*
Nothing	0		2,451.0	4,742.0
Nitrate of soda	50.00	At sowing time	2,780.5	6,330.0
Do	50.00	At germination	2,953.7	5,796.2
Do	50.00	½ at germination ½ at heading	3,025.0	4,912.5
Fish guano	33.75	Preceding fall	2,641.0	5,508.0
Do	50.00	do	2,643.7	5,218.7
Oats.				
Nothing	0		2,608.5	4,888.0
Nitrate of soda	33.75	At sowing time	3,137.5	5,833.0
Do	33.75	At germination	2,923.5	5,633.0
Do	33.75	½ at germination ½ at heading	2,731.5	5,810.0
Fish guano	33.75	Preceding fall	2,808.3	5,045.0
Do	50.00	do	2,833.3	5,223.0

The best time for applying nitrate of soda to spring wheat was at the time of germination or half at this time and half when the wheat was heading. In case of the oats, on the other hand, the best results were obtained by applying the fertilizer at time of sowing.

Barnyard manure vs. poudrette for winter wheat and other crops.—Beginning in 1891 straw-litter manure and peat-litter manure were compared with peat poudrette as fertilizers for winter wheat. In 1892 ruta-bagas were planted on plats 148.5 square meters in area, the barnyard manure being applied at the rate of approximately 40,000 kg. per hectare, and the poudrette at the rate of 15,000 kg. The poudrette used contained 74.70 per cent of water, 0.86 per cent of nitrogen, 0.45 per cent of phosphoric acid, and 0.44 per cent of potash. The yield of ruta-bagas per hectare was:

	Kilograms.
With straw-litter manure	41,073
With peat-litter manure	43,875
With peat poudrette	43,807

The yield was smallest with straw-litter manure, as it was also in 1891. The residual effect of the 3 kinds of manure was studied during 1893, barley being sown without fertilizers on the plats used in the preceding year's experiments. The yield of barley per hectare was as follows:

Residual effect of manures on yield per acre of barley.

Kind of fertilizer applied to the preceding crop.	Grain.	Straw.
	Kg.	*Kg.*
Straw-litter manure	3,663	5,855
Peat-litter manure	3,880	5,788
Peat poudrette	3,930	5,183

The results of 3 years' experiments show that even for heavy clay the peat-litter manure is superior to straw-litter manure.

Poudrette and nitrate of soda for various crops.—The effect of 3 kinds of poudrette on the yields of hay and of potatoes and on the starch content of the latter was studied in 1892 and 1893. The composition of the poudrette applied was as follows:

Analyses of poudrette.

	Water.	Total nitrogen.	Phosphoric acid.	Potash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Peat poudrette	70.70	0.86	0.40	0.44
"Riddersirk" poudrette	77.25	1.10	.74	.40
"Concentrated peat poudrette"	49.57	1.68	2.04	1.51

Only "Riddersirk" poudrette increased the yield of hay sufficiently to be profitable.

In 1893 the different kinds of poudrettes and nitrate of soda were compared on potatoes. As in 1892, like money values of the different fertilizers were applied. The soil was a sandy clay. The fertilizers were applied directly before planting the potatoes. The results follow:

Starch content and yield of potatoes.

Fertilizer.	Starch content.	Yield per hectare.	
		Tubers.	Starch.
	Per cent.	*Kg.*	*Kg.*
None	13.43	21,800	2,918
Peat poudrette	13.60	24,025	3,255
"Riddersirk" poudrette	13.66	24,650	3,360
"Concentrated peat poudrette"	13.80	21,000	2,905
Nitrate of soda	11.50	20,925	2,406

The low percentages of starch obtained are explained by the lack of rain in the early vegetation period, the low summer temperature, and the lack of heat and light during the month of September.

The decrease in the starch content of the potatoes receiving nitrate of soda is contrary to the experience of Stutzer, who states that the quality of potatoes is not appreciably lowered by applications of this fertilizer, and that the increase in yield is large, especially in dry seasons.

The effect of peat poudrette and nitrate of soda on barley was studied during 1893, equal money values of both fertilizers being applied. Every plat received Thomas slag at the rate of 80 kg. per hectare. The average results obtained were as follows:

Yield of barley with peat poudrette and nitrate of soda.

Fertilizer.	Yield per hectare.	
	Grain.	Straw and chaff.
	Kg.	*Kg.*
No nitrogenous fertilizer	2,433.0	6,176.5
Peat poudrette, spring 1893	3,139.0	8,037.0
Peat poudrette, fall 1892	2,627.0	6,742.5
Nitrate of soda	3,429.0	8,768.5

Phosphatic slag for potatoes.—The effect of 3 kinds of phosphatic slag on potatoes was investigated during 1893. "Finshytte" slag is made from ferruginous Gellivara apatite and is named after the place of manufacture. Martin's slag is obtained by treatment of Gellivara iron ore in the Martin process. These 2 slags contained 10.94 per cent and 17.83 per cent of phosphoric acid, respectively, while the Thomas slag applied contained 18.54 per cent of this ingredient. The plats were fertilized in the fall of 1892 at the rate of 100 kg. of potash per acre, in the form of sulphate, and 120 kg. of phosphoric acid in the different phosphatic slags; 2 plats received only potassium sulphate.

The average results for the duplicate plats were as follows:

The starch content and yield of potatoes.

Fertilizer per hectare.	Starch content.	Yield per hectare.	
		Tubers.	Starch.
	Per cent.	*Kg.*	*Kg.*
100 kg. sulphate of potash	13.1	10,941	1,433.27
100 kg. sulphate of potash 120 kg. phosphoric acid in Thomas slag	12.8	13,815	1,768.32
100 kg. sulphate of potash 120 kg. phosphoric acid in Martin's slag	12.5	14,648	1,831.00
100 kg. sulphate of potash 120 kg. phosphoric acid in Finshytte slag	11.9	11,471	1,365.04

Lemström's frost torches (E. S. R., 5, pp. 660–662) were used with marked success in the preceding experiments for preventing frost on the potatoes during several nights in the month of August. In the opinion of the author the Lemström peat frost torches are the most convenient, effective, and inexpensive combustive material for the generation of smoke as a preventive of damage from frost. The expense of torches is exceedingly small compared with the value of the crops in danger. Less than 100 torches are required per acre of land, the cost of which in the European market is given as 64 cts.—F. W. WOLL.

Rotation of crops, J. B. LAWES and J. H. GILBERT (*Jour. Roy. Agr. Soc. England, 3d ser., 5 (1894), No. 20, pp. 585–646*).—This is a comprehensive discussion of the results of rotation experiments at Rothamsted, England, begun in 1848. The four-course rotation consisted of (1) Swedish turnips (ruta-bagas), (2) barley, (3) clover (or beans) or bare fallow, and (4) wheat. One section of the field has received no fertilizers since the experiments began. On the other two sections fertilizers were applied only to the root crop, hence only once in 4 years. In the second section minerals only were used, superphosphate alone being applied in the first 9 courses (36 years), supplemented in succeeding courses by salts of potash, soda, and magnesia. The third section of the field received a complete fertilizer, supplying, in addition to minerals, 140 lbs. of nitrogen every fourth year, equivalent to an average annual application of 35 lbs. per acre. This complete fertilizer consisted of superphosphate, salts of potash, soda, and magnesia, and rape cake.

In each section the turnips on half the area devoted to this crop were fed on the land; on the other half both roots and leaves were permanently removed.

Crop yields under different conditions.—The turnip crop, sometimes regarded as a restorative crop, gave practically no yield without fertilizers. Superphosphate largely increased the yield, a result regarded as largely due to its increasing the growth of feeding roots in the surface soil, and thus enabling the turnip crop to quite completely exhaust the nitrogen previously accumulated in the soil. Hence soil fertility is very rapidly exhausted by growing and removing a turnip crop fertilized with superphosphate alone.

The addition of nitrogen to the mineral fertilizer practically doubled the yield obtained from superphosphate.

On the unmanured section the crop of turnips was so small that it mattered little, as shown by subsequent crops, whether it was removed or retained. On the section treated with superphosphate, feeding turnips on the land increased the yield, and the advantage of this practice was still more marked on the more productive area supplied with a complete fertilizer. The yield of turnips was practically identical whether the field was fallowed or in a leguminous crop 2 years previous.

Barley, the second crop of the course, suffered less from the absence of fertilizers than did turnips, the average yield of the unfertilized section being more than 30 bu. per acre. This was attributed to the thorough preparation for barley, viz, the clean cultivation of turnips, and to the slight draft made on the soil by the small (unfertilized) turnip crop. Naturally the removal or retention of the small turnip crop did not affect the yield of barley. On the plats on which turnips treated with superphosphate had yielded fairly well, the feeding of the turnips on the land considerably increased the yield of barley. However, on the section thus manured the removal of the turnip crop so far exhausted the soil as to reduce the yield of barley below the yield on the unfertilized section. A complete fertilizer applied to the preceding turnip crop largely increased the yield of barley, especially on the plats on which the heavy turnip crop had been fed.

Clover was intended to be the third crop of every course, but repeated failures of this crop led to the frequent substitution of beans in its stead. Thus in the 11 courses clover was grown only 4 times, beans 7 times. The yield of clover without manure averaged 3,000 lbs. per acre, which amount was doubled by superphosphate or mixed minerals, and raised to 6,800 lbs. when a complete fertilizer was applied to the turnip crop 2 years previous. The action of these fertilizers on beans was somewhat similar. Both beans and clover yielded better on plats where the turnip crop grown 2 years before had been fed on the land than on the plats whence it had been removed.

Both mixed minerals and a complete fertilizer applied to turnips increased the yield of wheat in the fourth year after the application. The retention of the turnips somewhat increased the yield of wheat in the fourth year thereafter.

On the unfertilized section and on that which had received minerals alone, on both of which there was soil exhaustion, especially of nitrogen, the wheat crop was somewhat larger after bare fallow than after the leguminous crop which had been removed. On the other hand, the section kept in a high state of fertility by the application of a complete fertilizer to turnips, and thus capacitated for a luxuriant growth of beans or clover (having a heavy crop residue), afforded larger returns in wheat when this latter crop followed a leguminous crop than when it was preceded by bare fallow. Thus on fertile soil the advantage of growing a leguminous crop instead of fallowing consisted not only in the value of the leguminous crop, but also in a slight increase in the wheat crop. Subsequent turnip crops showed no marked difference between the plats fallowed or bearing a leguminous crop 2 years previous.

Amounts of dry matter contained in the crops.—The amount of dry matter, nitrogen, ash, phosphoric acid, and potash in turnips, barley, clover and beans, and wheat, in rotation and in continuous culture, are tabulated and discussed.

The dry matter in turnips grown without fertilizer was practically identical in rotation and in continuous culture, due to the failure of the unfertilized crop grown under both conditions. When fertilized, the turnip yielded more in rotation than in continuous culture.

On the unfertilized section the grain and straw of barley grown continuously contained only about three fifths as much dry matter as in rotation, and on the mixed mineral section considerably less than in rotation. Especially marked was the difference in favor of rotation on the area where turnips had been fed. On the section supplied with a complete fertilizer continuous culture gave best results when the turnip crop of the rotation was removed, but rotation excelled when the turnips were fed.

Under all conditions of manuring beans grown continuously yielded only about half as much as when grown in rotation. A similar comparison could not be made for clover, because the crop failed so frequently.

In the wheat crop the dry matter obtained by continuous culture was, on the unfertilized section and on that receiving superphosphate alone, less than half as much, and on the section treated with a complete fertilizer, considerably less than that secured in rotation.

Amounts of nitrogen contained in the crops.—Only an inconsiderable amount of nitrogen was contained in turnips not fertilized. The amount was increased twofold to fourfold under the influence of phosphatic fertilizers alone, which induced the growth of numerous fibrous feeding roots. With a complete fertilizer the amount of nitrogen in the crop was greatly increased in both systems of culture. The large turnip crops obtained by the aid of nitrogenous manures on land which for about fifty years had received no carbonaceous application indicates that the atmosphere is "the chief, if not the exclusive, source of the carbon of the crops."

The nitrogen taken up by barley on the superphosphate section and on the unfertilized plat was considerably greater in rotation than in continuous culture. With a complete fertilizer barley in rotation took up less nitrogen on the plats from which the turnip crop had been removed than in continuous culture. Under all conditions of manuring, about 75 per cent of the nitrogen of the barley crop was contained in the grain.

Beans in rotation took up more than twice as much nitrogen as in continuous culture. In rotation the amounts were 36 lbs. per acre per annum on the unfertilized section, 40 to 50 lbs. with superphosphate, and 63.6 to 70.2 lbs. with a complete fertilizer. Under all conditions clover took up much more nitrogen than beans—without manure, 47 to 55 lbs.; with superphosphate alone, 124.5 to 144.6 lbs.; with a complete fertilizer 167 to 168.4 lbs. per acre. Of the nitrogen in the bean crop (beans and straw) at least 75 per cent was in the beans.

Wheat under all conditions of fertilization utilized more nitrogen in rotation than in continuous culture. Continuous culture gave more nearly equal results when a complete fertilizer was employed. Under all conditions the grain stored up more than twice as much nitrogen as the straw.

Amounts of phosphoric acid in the crops.—Only about half as much phosphoric acid was taken up by the turnip crop in continuous culture as in rotation, due to the unfavorable mechanical effects of the former system by which the total crop was reduced. In rotation and when well fertilized, 5 to 6 times as much phosphoric acid was accumulated in the roots as in the leaves.

Without fertilizers and also with superphosphate, barley took up much more phosphoric acid in rotation than in continuous culture; with a complete fertilizer the two systems of culture gave equal results when turnips were fed on the land, but when removed the rotation crops stored up less phosphoric acid than those under continuous culture.

Clover and beans under all conditions of manuring took up much more phosphoric acid in rotation than in continuous culture. Without fertilizers clover utilized but little more of this ingredient than beans; with superphosphate more than twice as much; and with a complete fertilizer still more. The draft of phosphoric acid was less with the leguminous crops than with the cereals.

Wheat, like barley, took up more phosphoric acid in rotation than in continuous culture. Without fertilizers and also with superphosphates about four fifths of this ingredient was stored in the grain. However, with a complete fertilizer, inducing luxuriant growth, the grain contained only about half the phosphoric acid, the rest being stored in the straw.

Amounts of potash in the crops.—The authors have shown elsewhere that root crops are essentially sugar crops, and that the presence of considerable potash is an important condition in the formation within plants of carbohydrates and especially of sugar. Most of the potash of the turnip crop was found in the roots and this proportion increased with the yield of the crop, the bulk of the potash and sugar being stored in the same part of the plant.

In turnip roots and leaves on the rotation plats, unfertilized, the amount of potash per acre was 4 to 6 lbs.; on the superphosphate plat 25 to 28 lbs., due to the increased feeding capacity resulting from phosphatic fertilizer; and on the area receiving a complete fertilizer 80 lbs. Less potash was utilized in continuous culture than in rotation.

In barley the greater portion of the potash was found in the straw. The amount of potash in the straw was subject to great fluctuations, depending on the supply in the soil and fertilizer, while that in the grain bore a fairly uniform relation to the dry matter.

Without fertilizers and with superphosphate the amounts of potash in the barley crop were not widely different, but with a complete fertilizer the quantity was largely increased. With a complete fertilizer and on a rotation plat from which the root crop had not been removed, the potash in rotation and in continuous culture crops was practically identical.

Beans took up about twice as much potash in rotation as in continuous culture. Without fertilizer and with superphosphate alone the quantaties of potash were practically the same, but with a complete fertilizer these amounts were doubled. Compared with beans grown under parallel conditions clover utilized much more potash; without fertilization, 3 times as much (30 lbs. per acre); with superphosphate alone, more than 5 times as much (57.6 to 65.5 lbs. per acre); and with a complete fertilizer, also more than 5 times as much (123.1 to 132.6 lbs. per acre).

The beneficial effect on clover of superphosphate used alone appeared to be closely connected with the increased capacity thereby conferred on clover of taking up larger quantities of the potash of the soil. In beans more than two thirds of the total potash was found in the seed.

Wheat in rotation took up much more potash than in continuous culture. As with barley, the greater part of the potash was found in the straw, which also contained the bulk of the carbohydrates in the form of cellulose.

The conclusion that phosphoric acid is specially concerned in the formation of the nitrogenous bodies and that potash is likewise related to the non-nitrogenous compounds, though regarded as well founded by the authors, offers only an imperfect explanation of the functions of these mineral constitutents.

Of all the crops of the four-course rotation the leguminous crops take up the most lime, clover sometimes utilizing more than all the other crops of the rotation taken collectively.

Cost and profit of growing wheat, B. C. BUFFUM (*Wyoming Sta. Rpt. 1894, pp. 14, 15*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 44).

On the decortication of wheat, BALLAND (*Compt. Rend., 120 (1895), No. 11, pp. 638–640*).

Industrial plants (Les plantes industrielles, IV), G. HEUZÈ (*Paris*).—This volume is chiefly occupied with tobacco and other narcotic plants, sugar-producing plants, gum-producing plants, medicinal plants, and tea and coffee.

Crop report for 1893, B. C. BUFFUM (*Wyoming Sta. Rpt. 1894, pp. 3–13*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 44).

The system and methods practiced at the station farm, R. J. REDDING (*Georgia Sta. Bul. 27, pp. 211–215*).—This is a general statement of the methods of rotation, fertilization, planting, and cultivation practiced on the station farm.

HORTICULTURE.

Tests of plums, apricots, and Japanese persimmons, R. H. PRICE (*Texas Sta. Bul. 32, pp. 473–496, figs. 13*).—This bulletin is chiefly devoted to comparative investigations as to the value of different varieties of plums in Texas. The varieties are arranged according to the natural classification of the species from which they have originated. Descriptive notes are given for 19 varieties of the Chickasaw group (*Prunus angustifolia*), 8 of the Wild Goose group (*P. hortulana*), 5 of the American group (*P. americana*), 9 of the European varieties (*P. domestica*), and 17 of the Japan group (*P. triflora*). In addition 8 unclassified varieties were tested, as were also *Prunus pissardii*, *P. simonii*, and the Utah hybrid dwarf cherry. Over 20 varieties of plums are stated to have originated in Texas, most of them belonging to the Chickasaw group, which succeeds better in the State than the Wild Goose or American groups of varieties, being more productive and freer from insect and fungus injuries. The following varieties are recommended: Caddo Chief, Lone Star, Marianna, Munson, Newman, Paris Belle, Robinson, and Transparent. The European varieties were not satisfactory, but the Japanese plums proved successful, although requiring spraying. Of them Abundance, Burbank, Douglas, Georgeson, Kelsey, and Norman are regarded as promising.

A table is given showing the dates of blooming and ripening of 67 varieties. Experiments were made with the Marianna plum to ascertain its value as a stock for budding, and several nurserymen were questioned in regard to this point. The conclusion arrived at is that the Marianna does not do well as a stock for all varieties, especially on dry uplands.

Brief notes are given on the curculio (*Conotrachelus nenuphar*) and leaf-footed bug (*Leptoglossus phyllopus*), and on the leaf blight, brown rot, and shot-hole fungus. Spraying the trees with 3 oz. of London purple mixed with 25 gal. of Bordeaux mixture is believed to prevent injury by nearly all injurious insects and fungus diseases.

Varieties of 2 species of apricots were tested, 4 varieties of the Chinese or Japanese apricot (*Prunus mume*) and 8 of the common and Russian apricots (*P. armeniaca*) being grown. Myer Early and Royal were most promising.

Ten varieties of the Japanese persimmon (*Diospyros kaki*) were tested, and Hachiya, Tane-Nashi, and Zengi are recommended.

The quince in western New York, L. H. BAILEY (*New York Cornell Sta. Bul. 80, pp. 609–631*).

Synopsis.—General and more detailed directions for the care of quince orchards, with remarks on the choicer varieties and notes on insect and fungus enemies.

This bulletin deals with the quince industry in general and particularly in western New York, where the fruit is more extensively grown than elsewhere. Some of the large and successful orchards in the

State are mentioned and compared with others where careless cultivation makes the crop almost a failure. A heavy, moist clay loam, rendered friable by good cultivation, fertilizing, and draining, is considered to be the best soil for quinces, although they thrive upon lighter lands, where, however, they are shorter lived. In the way of fertilizers, 200 to 300 lbs. of muriate of potash per acre, applied broadcast and harrowed in, is advised, supplemented by 200 to 500 lbs. per acre of phosphoric acid in bone compounds or dissolved South Carolina rock. It is believed that the requisite nitrogen can be supplied by tillage, green manures, and barnyard manure. The common idea that salt is an indispensable quince fertilizer is believed to be erroneous.

Clean culture is strongly urged, and illustrations are given showing the difference in appearance between orchards allowed to run to sod and others where the ground is kept well stirred by shallow tillage. It is advised that sodded orchards be broken up by thorough harrowing in the spring.

Quinces are propagated by cuttings, stooling, apple-root grafting, and budding on quince stocks. Both of the latter methods are recommended, though budding seems to be preferred, the stock being the Angers quince imported from Europe. It is advised that quinces be planted 15 ft. apart each way to allow a sufficient growth to the trees and permit spraying. The top should be started 20 in. or less above the ground and the branches allowed to spread rapidly. Each winter it is recommended to shorten in the annual growth. By this means the fruit is thinned, for the terminal blooms are removed and the crop is borne on the side spurs, being also less liable to injury from winds.

Quince trees begin to bear when 5 or 6 years old and reach their full productiveness when 9 or 10 years planted. An average crop is 1 bu. of good fruit to a tree, but this yield may be even doubled occasionally. Care in picking and packing the crop is urged to avoid bruising and to secure a better appearance of the product.

The 4 leading varieties are Orange, Champion, Rea, and Meech, of which Orange is the most widely known and grown, although Champion has proved the most productive. Illustrated descriptions are given of these varieties. The Chinese or Hong Kong quince (*Pyrus cathayensis*) is mentioned, the fruit being large, often exceeding 2 lbs.

Descriptive notes and treatment are given for leaf blight and spot (*Entomosporium maculatum*), rust (*Rœstelia aurantiaca*), pear blight or fire blight, borer, codling moth, and quince curculio. For the first 2 diseases spraying with Bordeaux mixture is recommended, and experiments are cited showing its beneficial result. Pear blight is regarded as the most serious disease, and can only be treated by cutting off and burning all affected limbs. Digging out the borers, spraying for the codling moth with Paris green, and jarring the curculios on to sheets is advised.

Experiments with fruits and fruit trees, E. S. RICHMAN (*Utah Sta. Bul. 37, pp. 1–10*).—Descriptive notes on various varieties of strawberries, grapes, peaches, apricots, cherries, plums, pears, and apples grown on the station grounds. Notes are given on 14 varieties of strawberries, and Parker Earle, Sharpless, and Thompson No. 7 are recommended. Of the 17 varieties of grapes mentioned Concord, Delaware, Early Victor, and Massasoit are especially advised for planting in Utah. Thirteen varieties of peaches were tested, of which 5 proved to be too late. The early varieties, such as Early Rivers and Early St. John are recommended. The Russian apricots, of which 3 varieties were grown, proved constant and heavy bearers, but produced small fruit, and consequently are not considered so desirable as other larger varieties. On account of their hardiness, however, they are preferred to the larger tenderer varieties of the common apricot. Twelve varieties of cherries were grown, and the sour cherries, such as Mt. Large and Early Richmond, were found to thrive better than sweet cherries, which were not perfectly hardy.

Brief remarks are made on an experiment in giving young orchards different kinds of treatment, alfalfa, clover, timothy, and a mixture of timothy and clover being sown on 4 different plats. As a result after 3 years of this treatment the majority of the trees are dead, while check trees planted on well cultivated land are living and doing well.

Varieties of the strawberry, L. H. BAILEY (*New York Cornell Sta. Bul. 79, pp. 583–600, figs. 9, pl. 1*).—This bulletin consists of a tabulation of the replies received from 110 correspondents throughout the State in regard to the different varieties grown in their sections. The Wilson strawberry still appears to be the leading variety for general cultivation, followed by Crescent, Bubach, Haverland, Warfield, and Parker Earle. Each important strawberry center has its own list of favorites, varying according to locality; in Oswego County, for example, Parker Earle and Bubach are preferred to Wilson and Crescent. The most popular early variety is Michel, with Crescent ranking second. Parker Earle and Gandy are recommended as late berries. The Crescent is considered the most productive variety, with Wilson and Warfield ranking second and third. As shippers, Wilson, Parker Earle, and Warfield received the greatest number of votes. In regard to the best berry for home use 31 varieties are mentioned by 101 correspondents, Bubach, Crescent, Jessie, and Wilson receiving the most votes for this honor. In all 52 varieties are recommended, but the most prominent are Wilson, Crescent, Bubach, Haverland, Parker Earle, Warfield, Michel, Gandy, and Jessie.

Strawberries and grapes, M. J. HUFFINGTON (*Colorado Sta. Bul. 29, pp. 24*).—Cultural directions for strawberries and grapes, with comparative notes and tabulated data for the varieties grown on the station grounds. For strawberries light or sandy soils are regarded as giving earlier fruit, while the crop is generally heavier on land possessing some clay. Irrigation is advised in some cases, and potash fertilizers and well-rotted barnyard manure are recommended. The yield of fruit was increased by nitrate of soda applied as a top dressing early in the spring. Mulching is regarded as advantageous because, besides protecting the plants during the winter, it retards their growth in the spring, and thereby lessens the chances of their being killed by late frosts. Thirty-eight varieties were tested, and the dates of blooming and ripening are given. Michel Early is recommended as a desirable extra early berry, while the most attractive berry in appearance and flavor was Edward Favorite. For market varieties are recommended Warfield, Parker Earle, Edward Favorite, Boynton, and Woolverton.

For grapes a warm, well-drained soil, sloping toward the south, is recommended, the vines to be set out in the spring in holes filled in with rich fertilizing substances. Pruning and training on trellises after the fan system is advised, each year trimming down the horizontal shoots to 1 or 2 good buds each. Notes are given for 22 black, 13 red, and 13 white varieties, and the following varieties, in the order of ripening, are recommended for the northern and eastern portions of the State: *Black*—Champion, Moore Early, August Giant, Oriental, Worden; *red*—Brighton, Norfolk, Delaware, Agawam; *white*—Eldorado, Moore Diamond, Martha, Lady Washington.

Asparagus growing, T. V. MUNSON (*Amer. Hort., 5 (1895), No. 2, p. 20*).—A short note on preferred methods.

Experiments toward the protection and improving of asparagus culture (*Ztschr. landw. Ver. Hessen, 1895, No. 4, pp. 27, 28, figs. 3*).

Asparagus culture on a large scale (*Tirol. landw. Blätter, 14 (1895), No. 5, pp. 44–46*).

Sweet potatoes, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Bul. 31, pp. 16–19*).—The Yellow Yam and Vineless were tested at Newport and at Camden. As a food for hogs the Vineless was preferred. Directions for the cultivation of sweet potatoes are given.

Garden vegetables and tobacco, B. C. BUFFUM (*Wyoming Sta. Rpt. 1894, pp. 24–30*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 133).

The Vitis æstivalis group of wine grapes, F. A. WAUGH (*Amer. Hort., 5 (1895), No. 2, pp. 18–20, figs. 2*).—Descriptive and comparative notes on some of the leading varieties of this group, Herman Jaeger, Jaquez, Norton Virginia, Herbemont, and Cynthiana being figured. The last two are considered especially valuable for wine.

The fertilizing constituents removed from the soil in wine, A. MÜNTZ (*Jour. Agr. Prat., 59 (1895), No. 13, pp. 472, 473*).

Chestnuts, W. A. TAYLOR (*Amer. Hort., 5 (1895), No. 2, pp. 28, 29*).—The Spanish and Japanese varieties are compared with the native chestnuts, and considered of inferior quality. Grafting the imported varieties on to American stocks is advised and further developing of choice varieties urged.

Notes on agriculture, B. D. HALSTED (*Science, n. ser., 1 (1895), No. 14, pp. 376–378, fig. 1*).—Notes are given on electro-horticulture, soil treatment of orchards for drought, Russian thistle, and beet leaf spot and its remedies.

Progress report on fruits and trees, B. C. BUFFUM (*Wyoming Sta. Rpt. 1894, pp. 31–34*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 55).

FORESTRY.

Osier culture, P. MOUILLEFERT (*Prog. Agr. et Vit., 12 (1895), No. 7, pp. 173–179*).

The bull pine in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), pp. 163, 164*).—Notes are given of *Pinus ponderosa,* showing its adaptability for planting in the Western States.

The Scotch pine in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), p. 142*).—The author states that where this tree has survived the first year no conifer gives better results in the West where tried than this one.

The white pine in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), p. 132*).

Pinus banksiana in the Nebraska sand hills, C. A. KEFFER (*Garden and Forest, 8 (1895), pp. 152, 153*).—A favorable report is given of experiments to grow this tree in the sand hills of western Nebraska.

Trees of minor importance for western planting, C. A. KEFFER (*Garden and Forest, 8 (1895), pp. 122, 123*).—Notes are given on ailanthus, Kentucky coffee trees, Russian poplars, and willows, sycamore, basswood or linn, plums, and choke and sand cherries.

Forestry and the abandoned farm, C. S. PLUMB (*Garden and Forest, 8 (1895), p. 162*).

Forestry at Michigan Agricultural College, W. J. BEAL (*Garden and Forest, 8 (1895), pp. 148, 149*).

Ornamental, forest, and shade trees, E. S. RICHMAN (*Utah Sta. Bul. 37, pp. 11, 12*).—Note on the trees growing at the station, the poplars being recommended as the most promising for general forestry purposes, while it is believed that the growing of some of the hard-wood trees, such as the black and white walnuts and ash, can probably be made profitable.

Forest trees, B. C. BUFFUM (*Wyoming Sta. Rpt. 1894, pp. 34, 35*).—A reprint from Bulletin 17 of the station (E. S. R., 6, p. 56).

SEEDS—WEEDS.

Further studies of the weed seeds found in American clover seed, O. BURCHARD (*Landw. Vers. Stat., 45 (1895), No. 5 and 6, pp. 469–476, tables 2*).—This article is a continuation of a previous paper[1] of the author on the origin of American clover seed as determined by the accompanying weed seeds. In the present article detailed descriptions are given of what the author considers some of the more characteristic weed seeds found in clover seed imported from this country. The following are described and most of them are illustrated by means of photogravures: *Teucrium canadense, Euphorbia preslii, Phacelia tanacetifolia, Paspalum læve, P. ciliatifolium, Solanaceæ "E," Euphorbia "D," Tiliaceæ "A," Hyoscris scabra, Hedeoma pulegeoides,* and *Plantago hookeriana* [probably *P. aristata*].

Effect of alkaloids on the germination and development of seeds, M. MOSSO (*Arch. ital. Biol., vol. 21, p. 231; abs. in Chem. Ztg., 18 (1894), No. 102, Repert., p. 328*).—The author made an investigation of the effect of various alkaloids on the germination and growth of seeds of *Phaseolus multiflorus.* The following were used in solutions of 0.0001, 0.0005, 0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, and 2 gm. in 100 cc. distilled water: Morphin, nicotin, cocain hydrochlorate, strychnin, atropin sulphate, and caffein salicylate. The experiment was conducted for 18 days, and comparisons were made with equal lots of seed soaked with water. It was found that cocain and atropin 0.01 per cent, strychnin 0.05 per cent, morphin 0.001, and atropin 0.0005 hastened germination, while the more concentrated strengths delayed it. For the caffein no accelerated results were secured, due, in the author's opinion, to the action of the salicylic acid. The author believes that alkaloids will have a narcotic or stimulating effect on plants as well as on animals according to the dose.

---

[1] Landw. Vers. Stat., 43 (1893), No. 3 and 4, p. 239 (E. S. R., 5, p. 911).

The influence of certain salts on germination, A. BRUTTINI (*Staz. Sper. Agr. Ital., 27 (1894), p. 30; abs. in Chem. Ztg., 18 (1894), No. 102, Repert., p. 328*).—The author conducted experiments on wheat with 1 and 2 per cent solutions of the substances mentioned below, the seed being soaked for 24 hours prior to planting. Each lot contained 15 seeds, and at the end of 4 days the following germinations were shown:

Germination of wheat treated with various salts.

Kind of salt.	Number of seed germinated.		Kind of salt.	Number of seed germinated.	
	2 per cent.	1 per cent.		2 per cent.	1 per cent.
Mercuric chlorid	0	0	Potassium sulphocyanid	10	14
Ferric chlorid	0	2	Uranium nitrate	10	13
Platinum chlorid	3	6	Cobalt chlorid	11	14
Potassium cyanid	4	6	Potassium phosphate	12	14
Copper nitrate	5	6	Potassium ferrocyanid	12	13
Manganese phosphate	5	7	Sodium chlorid	12	13
Barium permanganate	6	8	Calcium chlorid	12	15
Nickel chlorid	6	9	Potassium permanganate	13	14
Ammonium chlorid	7	12	Barium chlorid	13	13
Ammonium sulphocyanid	8	12	Potassium nitrate	15	15
Copper sulphate	9	13	Distilled water	15	15
Potassium ferricyanid	9	13			

The germination of seed, WERNICKE (*Ztschr. landw. Ver. Hessen, 1895, No. 8, pp. 57, 58*).—The author experimented with various seeds which, owing to their thick or nearly impervious seed coats, are usually very slow in germinating. The ones experimented upon were *Acacia molissima* and *Lathyrus* spp. particularly *L. sylvestris wagneri*. He subjected them to hot water for various times, after which the seeds were planted in sand in flower pots. Seeds without any treatment gave 50 per cent germination, those soaked for 6 hours in water at 122° F. gave 60 per cent, those soaked for 3 hours at 167° F. gave 72 per cent, and those treated for an hour with water heated from 204 to 212° F. gave 92 per cent germination.

Squirrel-tail grass, A. NELSON (*Wyoming Sta. Rpt. 1894, pp. 73-79, pls. 4, fig. 1*).—A reprint of Bulletin 19 of the station (E. S. R., 6, p. 640).

DISEASES OF PLANTS.

Some fungus diseases of beets, B. D. HALSTED (*New Jersey Stas. Bul. 107, pp. 13, figs. 5*).

Synopsis.—The author reports upon beet scab, root rot of beets, leaf spot, beet rust, white rust, and downy mildew.

Beet scab (pp. 3, 4).—The identity of the scab of beets and potatoes[1] is mentioned, and the necessity of avoiding the planting of one crop where a diseased crop of the other has previously grown.

Root rot of beets (pp. 4–6).—While examining a store pit of beets a fungus was obtained which affected the roots, causing them to be slightly shrunken and almost coal black in color, this discoloration sometimes extending fully to the center of the root. The surface or affected part was dotted with minute specks, which upon examination proved to be the pycnidia of a species of *Phyllosticta.* When placed in moist cloths and kept warm the young patches on the diseased roots soon develop the pycnidia in abundance. It was noticed that the fungus easily penetrates the cloth and develops the pycnidia on its upper surface; and this fact was taken advantage of by the author to secure, in a comparatively easy way, pure cultures of the fungus. Two years before a *Phyllosticta* was found upon the leaves of garden beets, and a comparison of the pycnidia taken from the roots in question and compared with those on the leaves showed that they are probably the same species. It was noticed that the beets in the storage pit in several instances still had adhering to them shreds of old leaves, and in some cases the patches of decay were located beneath such closely adhering leaves. Healthy roots obtained from a field where no *Phyllosticta* was found on the foliage were placed in a box and surrounded with fresh leaves obtained from a field at a considerable distance. In 10 days several diseased patches developed upon the surface of the beets and appeared the same as those previously studied. As the leaf is more susceptible to the disease than the root the author thinks a practical preventive of the spread of the disease to the root may be secured by exercising care in the removal of all foliage before roots are stored.

Beet leaf spot (pp. 7–11).—This is a leading fungus disease of the beet in New Jersey and is caused by *Cercospora beticola.* It seems to affect all varieties of the beet, and makes no distinction between the early and later planted ones. Its appearance upon the leaves is first noticed by the presence of small, light, ashy colored spots, which later often become holes by the disappearance of the tissue previously killed by the fungus. During the past season field experiments were made with fungicides for the prevention of this disease. The ones tested were Bordeaux mixture and ammoniacal copper carbonate, each being used in three strengths. The Bordeaux mixture full strength was made from freshly slacked lime and sulphate of copper, each 5 lbs., and water 25 gal., the other strengths being made by increasing the amount of water so as to make solutions of one half and one fourth strength. The ammoniacal copper compound for full strength consisted of 5 oz. of copper carbonate dissolved in 3 qt. of ammonia and 30 gal. of water. For the weaker solutions water was added to secure the one half and one fourth strength. The sprayings were begun on June 21, when the beets were 6 weeks old, and were continued at intervals of 10 days until 10 sprayings had been made. All the ammoniacal solutions were too strong, the foliage being burned wherever they were used.

---

[1] North Dakota Bul. 4 (E. S. R., 3, p. 619).

The use of Bordeaux mixture caused so striking a difference in the plants as to be readily observed in passing the field. The untreated rows had small foliage, more upright and badly spotted leaves, while the sprayed plants showed a rank growth of leaves, nearly green throughout, with much less spot than the untreated plants. The usefulness of Bordeaux mixture as an insecticide was shown in one instance. The insects, which had been feeding on turnips, invaded the beet field, in some instances stripping the foliage of the untreated rows; those treated with Bordeaux mixture were left free. An increase of nearly 26 per cent in weight of plants was secured from the plants on which the Bordeaux mixture had been used, showing that the leaf spot of beet can in a large measure be controlled by the use of this fungicide.

Beet rust (p. 11).—The beet rust (*Uromyces betæ*) has not yet appeared in New Jersey, but the author gives a brief description of it and advises growers to be on the lookout for its appearance.

White rust of beets (p. 11).—This disease, caused by *Cystopus blitii*, is mentioned as a possible enemy. Probably the same fungus is not uncommon upon various weeds, *Amarantus* and the *Blitum*, spp.; and such weeds should be destroyed lest they spread the disease to the beet.

Downy mildew (p. 13).—This disease, caused by *Peronospora schachtii*, is briefly described, but it has not yet appeared in this country.

Further observations upon the effect of soil conditions upon the development of the potato scab, H. J. WHEELER, J. D. TOWAR, and G. M. TUCKER (*Rhode Island Sta. Bul. 30, pp. 66–85, figs. 22*).—In this bulletin is given a continuation of investigations of the authors, reported in Bulletin 26 of the station (E. S. R., 5, p. 590), on the influence of air-slacked lime upon the development of potato scab. The authors are strongly inclined to question whether the corrosive sublimate, or any other treatment which does not seriously impair the vitality of the tuber, will destroy all germs on contaminated seed tubers.

A series of plat experiments was conducted in 1894 to test the effect of the use of lime on the acid soils of the station, the efficiency of the corrosive sublimate treatment, the value of soda as a substitute for potash, and pot experiments to determine the effect, if any, of using other forms of lime than carbonate.

In the first experiment the limed plats had received 2½ tons per acre of air-slacked lime in 1893, and ½ ton additional in 1894. One lot of seed tubers treated with corrosive sublimate was planted on soil that had not grown potatoes for many years. A second lot of untreated tubers was planted on soil supposed to be uncontaminated, while a third was planted on soil that had grown a crop of potatoes in 1893. The limed plats in all 3 cases produced scabbed potatoes, while the acid soils gave scabbed tubers only in 2 cases where untreated seed had been used. Sugar beets grown between the rows where no potatoes had been previously raised were in all cases free from scab, showing that the disease does not spread laterally with very great rapidity.

In the second experiment to test the value of the corrosive sublimate treatment, no potatoes had been grown on the plats for at least 10 years, and the application of lime was the same as in the previous experiment. The authors summarize their conclusions on this experiment as follows:

"(1) In every instance there is a greater percentage of scabbed tubers on the limed than on the unlimed sections where the seed tubers were not previously treated with corrosive sublimate solution.

"(2) The treatment with corrosive sublimate solution appears to have unquestionably reduced the percentage of scab upon the limed sections.

"(3) In case of the unlimed sections, there was in one instance a greater percentage of scab where the seed tubers received the corrosive sublimate treatment, while in the three other instances the per cent of scab was less. These results are contradictory in two instances, and in the other two the differences are so slight that as a whole no practical advantage from the treatment is apparent.

"(4) It will be seen that without exception some scab resulted on both limed and unlimed sections of the plat, even when the corrosive sublimate treatment of the seed tubers was employed. Bearing in mind that beets, grown in another place upon soil known to have been previously contaminated with the germs of the disease, were badly scabbed, and in consideration of the fact that beets have in no other instance been found to be scabbed when grown on any of the plats in the vicinity, we have striking circumstantial evidence from the scab upon the tubers grown from treated 'seed' that they probably owed their diseased condition to the introduction of undestroyed germs on the seed tubers and not to the preëxistence of the germs in the soil itself."

In the third experiment the primary result was not a study of potato scab, but the tabulated results show a tendency of lime to increase the potato scab.

In the pot experiments the object was to test the effect of different forms of lime on scab development. It is claimed that wherever lime in the form of carbonate or in forms capable of producing carbonates was used the per cent of scab was increased. Sulphate of lime gave conflicting results. Calcium chlorid gave least scab, but it injured the growth of the potatoes. No attempt is made to draw definite conclusions from this series of experiments.

The authors conclude as follows:

"Experiments with air-slacked lime covering a period of 2 years show conclusively that it tends to increase the scab of potatoes.

"Since wood ashes contain about one half as much lime in practically the same form, there remains almost no question but that they will also increase the scab. One ton of air-slacked lime contains in general a little less than 2 tons of wood ashes.

"It seems probable that the natural acidity or sourness of the soil tends to check the spread of the disease, and the tendency of barnyard manure to increase it may reasonably be attributed to its alkaline action, by which the sourness is overcome.

"If the farm stock is fed on scabbed beets or potatoes in an uncooked condition, then barnyard manure may still further increase the disease by carrying to the soil germs which have passed through the digestive organs of the animal undestroyed. If a soil is very acid small quantities of barnyard manure, wood ashes, and air-slacked lime will probably have far less tendency to increase the scab than when large quantities are used. The amounts which it would be safe to apply are doubtless dependent upon the sourness of the soil. The safest course, until absolutely effective means of disinfecting the seed tubers are found, would be to avoid these substances altogether, provided potatoes are to be grown successively or in frequent rotation upon the same land. Upon such soil lime not only increases the total yield but also the percentage of tubers of large size, so that if only one crop were to be grown the use of lime would prove decidedly beneficial, for the effects from the scab are not serious the first year. When grown under these conditions, the corrosive sublimate treatment has lessened decidedly the amount of scab. It is possible by the use of this treatment that potatoes may be grown upon limed soil successively or in frequent rotations without the arising of serious injury from the scab, yet our observations up to the present time make it appear very doubtful if this can be done."

Experiments conducted with about 50 agricultural plants show that lime favors the growth of most of them, and the development of scab on potatoes is the only drawback to its general use on acid soils that has so far been observed by the authors.

Report of the botanist, L. R. JONES (*Vermont Sta. Rpt. 1893, pp. 41-69, figs. 7*).—The author gives detailed reports on experiments in spraying potatoes; time and rate of growth of potato tubers and effect of premature death of potato tops on the yield; relation of time of planting potatoes to diseases; and a spray cart for potatoes. These different articles are in the main reprinted from Bulletin 40 of the station (E. S. R., 5, p. 988).

In the experiments in spraying potatoes the author reports in detail on the use of Bordeaux mixture, ammoniacal copper carbonate, copper and ammonium carbonate solution, modified eau celeste, sulphosteatite and copper sulphate of various strengths of solution. The author considers that Bordeaux mixture is the best fungicide for the prevention of potato diseases.

A report is given on the loss occasioned by oat smut in Vermont in 1893. Ninety-eight fields were sampled, the total number of heads examined being 39,826, showing that 0.82 per cent was smutted. A comparison of Vermont-grown seed with that grown in other localities shows less smut from the home-grown seed.

Black knot of plums and cherries and methods of treatment, E. G. LODEMAN (*New York Cornell Sta. Bul. 81, pp. 635-656, figs. 6*).—According to the author the black knot of plums and cherries, which is due to *Plowrightia morbosa*, was first troublesome in the eastern part of the United States, and it has spread westward through the introduction of diseased plants from the East. The life history of the fungus is given in considerable detail and various remedial treatments suggested. In 1893 some experiments were begun at the station for the prevention of the disease. A thicket of Morello cherry trees and sprouts was taken for the experiment, and 5 applications of Bordeaux mixture made in that year. In 1894, after 1 application of the fungicide, all the knots were cut out and counted on the treated and untreated portions of the plat. During this year 8 applications of Bordeaux mixture were made, and on November 26 the new knots were removed from both the sprayed and unsprayed portions. On April 25 the knots removed from the unsprayed portion were 2,002; the sprayed, 1,155. On November 26 the number of knots removed from the unsprayed portion was 3,529, of which 3,466 were new knots; from the sprayed portion 240 knots were removed, of which 165 were new, showing that the application of the fungicide had materially decreased the disease.

The author recommends the following treatment: Spray (1) during the latter part of March or early in April, (2) when the buds begin to swell, (3) as soon as the new knots begin to show their velvet coating, (4) at intervals of 2 or 3 weeks as may seem necessary.

As some of the applications for the control of black knot are made at a time when other diseases require treatment, but little extra labor is involved in the spraying for the prevention of knots. The author thinks that the spraying of plums and cherries to protect them from the black knot fungus can be carried on with profit in all sections where this disease threatens to interfere seriously with the profitable cultivation of these fruits. A bibliography of the black knot literature is included in the bulletin.

Aureobasidium vitis, G. DE LAMARLIERE (*Rev. Mycol., 17 (1895), No. 2, pp. 54–56*).—A review of recent literature, with critical notes.

Notes on Fusicoccum abietinum, R. FERRY (*Rev. Mycol., 17 (1895), No. 1, p. 25*).

Recent observations on the external characters of black knot, G. LAVERGNE and E. MARRE (*Rev. Vit., 2 (1894), p. 498*).

The bacterial gummosis of the grape, PRILLIEUX and DELACROIX (*Prog. Agr. et Vit., 12, (1895), No. 11, pp. 271–277; No. 12, pp. 312–321*).—Reprinted from *Annales de l'Institut Agronomique*.

Report on a disease of chestnuts in Bretagne, France, L. CRIÉ (*Bul. Min. Agr. France, 13 (1894), pp. 884–892*).

An orchid disease, G. MASSEE (*Ann. Bot., 9 (1895), No. 33, p. 170*).—A preliminary report is given of a brown spot disease of orchid leaves caused by *Plasmodiophora orchidis*. A more detailed description is promised later.

A disease of the plane tree, LECLERC DU SABLON (*Rev. Mycol., 17 (1895), No. 2, pp. 57–59, table 1*).—Illustrated description given of a disease due to *Glœosporium platani*.

The prevention of potato scab, L. R. TAFT (*Mich. Press Bul., Jan., 1895, pp. 4, figs. 3*).—Directions are given for the treatment of seed potatoes with corrosive sublimate for the prevention of scab.

The use of lysol to prevent mildew, L. DEGRULLY (*Prog. Agr. et Vit., 12 (1895), No. 14, p. 355*).—The author advises caution in its use and recommends that it should not be used in greater strength than 0.5 per cent.

New remedies for grape mildew, J. DUFOUR (*Chron. Agr. Canton Vaud., 8 (1895), No. 4, pp. 78–80*).—Methods for preparation are given for a copper and molasses mixture, copper and tannin mixture, lysol, and a powder from which Bordeaux mixture can be made.

The preparation of Bordeaux mixture, E. G. LODEMAN (*Garden and Forest, 8 (1895), pp. 159, 160*).—The author prefers weighing the substances to form the mixture or depending on the color to the potassium ferrocyanid test. He shows the necessity of an excess of lime in the mixture to prevent injurious changes that take place in neutral mixtures.

Bordeaux mixture and color tests, S. A. BEACH (*Garden and Forest, 8 (1895), p. 128*).—Notes are given on the use of potassium ferrocyanid in testing Bordeaux mixture, and where the preparation is in inexperienced hands the ordinary method of weighing is to be preferred.

A kerosene attachment for spraying pumps, E. S. GOFF (*Garden and Forest, 8 (1895), p. 143, figs. 2*).

How and when to spray (*Amer. Gard., 16 (1895), pp. 146, 147*).—A spray calendar with formulas for fungicides and insecticides is given.

Spraying potatoes, L. R. JONES (*Vermont Sta. Rpt. 1893, p. 20*).—A summary of Bulletin 40 of the station (E. S. R., 5, p. 988)

ENTOMOLOGY.

The cabbage root maggot, with notes on the onion maggot and allied insects, M. V. SLINGERLAND (*New York Cornell Sta. Bul. 78, pp. 481–577, figs. 18*).

Synopsis.—An elaborate illustrated paper on the cabbage root maggot (*Phorbia brassicæ*), giving in detail the description, life history, and the results of extended experiments with remedies against its ravages. Brief comparative notes are also given for several allied species. Injecting carbon bisulphid into the ground a few inches from each plant is recommended as the most effective method of destroying the pest, although the application of carbolic acid emulsion is also advised.

The work recounted in this bulletin was undertaken at the request of numerous cabbage growers on Long Island, where extensive growing of cabbages is done and where the cabbage root maggot for many years has proved a pest, annually destroying many acres of the vegetable. The insect was first noticed in the United States in 1835, being introduced from Europe into Massachusetts, and from there has since gradually spread over the greater portion of the United States and Canada, where it is now sufficiently abundant to destroy thousands of acres of cabbages, cauliflowers, radishes, and turnips every year. Although the favorite and presumably native food plant of the insect is *Brassica oleracea*, embracing the cabbages, kales, collards, brussels sprouts, cauliflower, and broccoli, quite a range of food plants is shown, apparently, however, confined chiefly to *Cruciferæ*. In addition to the vegetables mentioned the radish, turnip (*Brassica rapa*), ruta-baga and swede (*B. campestris*), common winter cress (*Barbarea vulgaris*), and hedge mustard (*Sisymbrium officinale*) are attacked. Breeding experiments, evidence of other observers, and comparative study of cabbage and radish maggots seem to indicate that the cabbage and the radish maggot are the same species. The similar maggots infesting onions, beans, and raspberry canes are different insects, distinct from each other and from the cabbage root maggot.

The plants first show the effects of the presence of the maggots after they have been set in the field 2 or 3 weeks, on Long Island about May 15, the time, however, varying with season, locality, and latitude. The first indication is shown by a checking of the growth of the plant, a tendency to wilt badly under a hot sun, and a sickly bluish cast to the foliage, following which the plant in a few days wilts, falls over, and dies. The result is affected by the size of the plant, the number of maggots at work, and the soil and weather conditions, a rich soil and plenty of moisture enabling the plants to withstand the attacks of the maggot for a long time.

"The full grown cabbage maggot is about 0.32 in. (8 mm.) in length, white, cylindrical, tapering cephalad and obliquely truncate caudad, with 12 fleshy tubercles around the caudal margin, the lower two of which are 2-toothed; and the cephalic spiracles have 12 divisions." The pupa is shorter, measuring about 0.2 in. in length, and is of an elliptical ovate form, and light brown, becoming darker with age. Specimens are easily found in the soil about infested plants in June.

Illustrations from micro-photographs of both sexes of the adults are given. By a casual observer the adult fly might be mistaken for the common house fly, which it resembles in general appearance, but from which it differs by its smaller size, being only about 0.2 in. (5 mm.) in length. The sexes differ considerably in appearance, as is shown by the following descriptions:

"The male fly is of a general dark ash-gray color, with 3 rather broad blackish dorsal stripes on the thorax, and a wide, black, dorsal stripe extending along the abdomen, becoming narrower toward its extremity and more or less dilated opposite the upper margin of each segment, which is marked with a narrower transverse black stripe. Many bristly hairs project from different parts of the body, and the abdomen is subcylindrical, narrow, and but slightly tapering. The eyes, occupying a greater portion of the head, nearly touch each other above. The legs are black and strongly bristled; on the under side of each hind femur near its base is a tuft of these bristles; which are characteristic of this cabbage fly. This tuft is quite noticeable on the femur of the male fly, especially when comparison is made with the corresponding femur of the female; by this character alone the male insect can be recognized and separated from the other common anthomyiian pests. There is also a characteristic row of short bristles, unequal in size, on the inner side of the hind tibia of the male insect that will help to distinguish the species.

"The female fly is of a lighter ash-gray color, quite indistinctly striped on the thorax and abdomen, and not so strongly bristled as the male. Her eyes are also quite widely separated above. The abdomen is of a more elongate ovate shape with a pointed apex. There seems to be no special characteristic by which the female fly can be recognized and separated from some of the other common anthomyiians; it is necessary that it be found associated with its male to determine it with certainty."

For comparison illustrated descriptions are given of the onion maggot (*Phorbia ceparum*), root maggot (*Anthomyia radicum*), and fringed anthomyiian (*Phorbia fusciceps*). The onion maggot closely resembles the cabbage root maggot in size, shape, and color, but differs in certain anatomical features, especially in the arrangement and number of the fleshy tubercles of the caudal segment. The adult onion fly resembles the cabbage fly, but is slightly larger, and the hind femur is comparatively bare of hair at the base, while in the cabbage fly the base of the femur carries a tuft of hair. The life histories are much the same. But one specimen of the root maggot has been taken in the United States, and therefore no immediate damage is anticipated from it. The maggots of the fringed anthomyiian are much smaller than the onion maggots or cabbage root maggots, and are not nearly so destructive to vegetation. They feed on a number of plants and also on the eggs of the Rocky Mountain locust.

The relation of the cabbage root maggot to the club root of cabbages, which is popularly supposed by gardeners to be caused by the insect, is discussed, and the disease is shown to be due to the cabbage slime mold (*Plasmodiophora brassicæ*). The disease and maggot attacks may, however, and frequently do, occur on the same plant.

The flies first appear in the latter part of April and the first of May, when the female flies may be seen running over the ground about the cabbage plants endeavoring to find some crevice by means of which they can creep beneath the surface of the soil and deposit their eggs close to the cabbage stem. About 55 eggs are probably laid by each fly, although some hundreds of eggs may be laid about a single plant by different flies. The eggs are white, irregularly ridged and grooved longitudinally on one side, and 0.04 in. in length. The eggs hatch in from 4 to 10 days, depending on the weather, but efforts made to breed the insect from eggs in confinement were unsuccessful. The young maggots immediately attack the surface of the root, rasping out burrows along the surface, and first devoting themselves to the rootlets, after which the main root is eaten and often girdled. The burrows are slimy, and the decaying roots upon the death of the plant give out a sickening odor. The larval stage is believed to be about 3 weeks, when the maggots work their way into the soil an inch or two from the roots and there pupate. The pupal stage continues from 15 days to over 3 months, but the majority of flies issue in about 20 days.

It has been believed that there are 3 or 4 annual broods of the insect, but the investigations show that there are but 2 distinct broods, with possibly a third. The flies of the first brood appear in April and shortly deposit their eggs, from which about three fourths of the second brood appear in June, the remainder emerging at varying times throughout the summer. The maggots of this second brood work on the plants in July, pupate, and some of them emerge as adults the latter part of that month or in August as a third brood, but the majority hibernate as pupæ to emerge the following spring.

As natural enemies are mentioned chickens and rooks, which are fond of the maggots, but in eating them usually pull up the cabbage plants, so that aid of this kind is not advised. In England several small hymenopters are parasitic to the cabbage root maggot, none of which are found in this country. However, a cynipid (*Trybliographa anthomyiæ*) has been bred from pupæ in various parts of the United States, and it is believed will play an important part in checking the pest. In addition a staphylinid beetle (*Aleochara nitida*), in both its larval and adult forms, attacks the maggots and pupæ. In some instances the larvæ of the beetle gnaw their way into the pupæ of the pest, devouring the contents, and undergo their metamorphoses within the shell. A species of *Trombidium* also is an enemy of the cabbage fly, sucking the eggs.

About 70 different methods have been recommended for combating the cabbage root maggot and many of them were employed in the experiments here given. Only 6 are regarded as effective and recommended to be employed, although 9 others are classed as doubtful or partially effective. The effective methods are divided into preventive and destructive measures. Frames covered with cheese cloth or fine netting and placed over the plants proved an efficient protection against the flies, but are only practicable with small areas and a few choice plants. Tarred paper cards cut hexagonally, with a slit reaching to the center, where a star-shaped cut was made to accommodate the stem of the plant, were applied to the young plants on setting them in the field, and pressed closely down to the surface of the ground. By this means the female fly was unable to get at the base of the stem to lay her eggs, and thus the plants were protected. Two rows of 300 plants each were protected by means of the tarred cards on April 19, and on May 21 less than 50 plants were attacked in each of the rows, while hardly 50 plants remained standing in 4 equal untreated rows used as checks. The cards were made of the paper called "1-ply tarred felt" and were cut out by a stamping tool 1½ in. on the side. This method is believed to afford almost complete protection to cabbages and cauliflowers.

Destructive measures, such as crushing the eggs by rubbing the stems of the cabbages with the fingers every few days and by hand picking the maggots, proved effectual, but the amount of work required will hardly recommend them. Two insecticidal substances proved very efficient, a carbolic acid emulsion and soil injections of carbon bisulphid. The carbolic acid emulsion was made by dissolving 1 lb. of hard soap or 1 qt. of soft soap in a gallon of boiling water, to which 1 pt. of crude carbolic acid was added, and the whole stirred into an emulsion. One part of this was added to 30 parts of water and poured around the bases of the plants, about 4 oz. being used at each application, beginning when the plants were set out and repeated every week or 10 days until the last of May. To bring about the best results some of the earth should be removed from about the plants before pouring on the emulsion. In the experiments none of the cabbages were injured. This method is believed to be a most successful and practicable one for treating radishes, turnips, or onions, but for cabbages and cauliflowers the application of carbon bisulphid is preferred. This is applied by means of a newly devised injector, consisting of a large syringe with a cylinder large enough to hold about 2 qt. of the chemical and so constructed as to deposit from a teaspoonful to a tablespoonful of the liquid at every motion of the piston. The nozzle of the instrument should be inserted into the soil 3 or 4 in. from the plant and pushed downward to a point a little below the roots. The chemical should then be expelled, the injector withdrawn, and the hole filled with earth by means of the foot. One injection is usually sufficient, to be given when the maggots have well appeared. The cost is about 1 ct. for every 10 plants.

The methods designated as doubtful or but partially effective are the application of gas lime, kerosene oil and sand, lime, and liquid manure to the soil, and the employment of cultivation. Of insecticides hellebore and kerosene emulsion produced conflicting results. The destruction of the pupæ by destroying the "old stumps," by fall plowing, and by the use of gas lime is also classed among these methods.

Among the numerous methods that have been thoroughly tested and found ineffective or impracticable may be mentioned soil selection, time of planting, trap crops, different fertilizing substances, rotation of crops, and various insecticides. Tobacco decoction and kainit are regarded as not having been sufficiently tested, but are not believed to be desirable.

In conclusion the bibliography and synonymy of the insect are worked up and its identity and relationships discussed.

Report of entomologist, G. H. PERKINS (*Vermont Sta. Rpt. 1893, pp. 119–145, figs. 19*).—Brief popular notes on insecticides and on various insects that proved more or less injurious throughout the State during the year, with prefatory remarks on the nature and methods of investigations in economic entomology and the care and perseverance required.

Directions are given for the preparation of various insecticides, and experiments are mentioned for proving their respective efficiency. Paris green and lime, and kerosene emulsion, are advised for insects attacking the foliage; dilute kerosene emulsion for root-infesting insects; and bisulphid of carbon for grain insects. Experience with potash salts used as fertilizers leads to the opinion that their insecticidal powers have been overrated.

An insect new to the State, *Catastega aceriella*, is mentioned as attacking maple leaves, constructing a web-covered tunnel on the undersides of the leaves. Considerable damage to the shade trees is feared, and spraying with Paris green or arsenate of lead as soon as the caterpillars appear in the spring is advised.

Illustrated descriptive, life history, and remedial notes are given for the horn fly (*Hæmatobia serrata*), apple maggot (*Trypeta pomonella*), and various cutworms, particularly the following: *Agrotis ypsilon*, *Peridroma saucia*, *Noctua clandestina*, *Feltia subgothica*, *Carneodes messoria*, *Mamestra subjuncta*, *Xylophasia devastatrix*, and *Nephelodes minians*.

The horn fly has spread over the most of the State and is causing more or less annoyance. Spraying infested cattle with kerosene, destroying the eggs of the flies by sprinkling quicklime over the droppings, and other common remedies are advised.

The life history of the apple maggot is given in detail, attention being called to the fact that the eggs are laid in the pulp of the apple instead of on the skin and that they are deposited from July until frost, thereby a continuous appearance of adults being provided. Destroying windfalls, preferably by turning hogs into the orchards, is recommended, and burning the grass during the winter in such orchards as are kept in sod. It is believed also that lime, ashes, salt, or similar substances applied to the ground will have the effect of destroying the larvæ at the time of pupation.

Twenty-six species of cutworms are cited as occurring in Vermont, but only those mentioned above are considered worthy of notice in detail. Poisoned trap food, fall plowing, and other usual treatment is recommended.

Habits and metamorphoses of insects (Coleoptera, Ptinidæ), IV, V. XAMBEU (*Ann. Soc. Ent. France, 63 (1894), pp. 459–504*).—The author introduces this paper with a general account of the characteristics of the larvæ and pupæ of European *Ptinidæ* (=subfamily *Ptininæ*, Lec. & Horn), their habits, mode of occurrence, and injuries done by them. The eggs of one species, *Ptinus irrotatus*, are described. Two hymenopterous parasites are mentioned, and one of them, *Scleroderma* sp., bred from the pupæ of *Ptinus brunneus*, is described in the larva and imago states. The larvæ of the following species of *Ptinidæ* are described in detail: *Hedobia pubescens*, *H. imperialis*, *Ptinus brunneus*, *P. dubius*, *P. ornatus*, *P. germanus*, *P. sexpunctatus*, *P. fur*, *P. aubei*, *P. irroratus*, *P. auberti*, *P. latro*, *Niptus submetallicus*, *N. crenatus*, *N. holosericeus*, *Mozium sulcatum* and *Gibbium scotias*. A bibliography of the biology and notes on geographical distribution conclude the article. Most of these species are of economic importance and a number of them occur also in North America, while others are sure to be imported in the course of time.—E. A. SCHWARZ.

Legislation against injurious insects, L. O. HOWARD (*U. S. Dept. Agr., Division of Entomology Bul. 33, pp. 46*).—This consists of a compilation of the laws and regulations in the United States and British Columbia regarding insecticide work, and providing for the inspection and quarantine of trees, shrubs, fruits, and other objects upon which injurious insects may be introduced. The legislation against injurious insects is quoted from the statutes of California, Oregon, Washington, Idaho, New Jersey, Colorado, Missouri, Kansas, Minnesota, Nebraska, and British Columbia. The laws are more extensive and comprehensive in California, Oregon, and other western States. In the west-central States the legislation is almost entirely against grasshoppers. In addition is given the legislation against foul brood in New York and Utah.

This compiled bulletin is issued to attract the attention of agriculturists and horticulturists toward the necessity for the passage of such laws and to form an easy source of information for persons engaged in the drafting of such regulations.

Spray calendar, E. G. LODEMAN (*New York Cornell Sta. Cir., Feb., 1895*).—This consists of a table showing the times, substances, and methods for spraying various orchard and small fruits and flowers, as preventive means against insects and fungus attacks. The directions for making the applications are briefly and concisely summarized in the different columns of the table. In addition formulas are given for the preparation of Bordeaux mixture, ammoniacal copper carbonate, copper sulphate solution, Paris green, London purple, hellebore, and kerosene emulsion.

Histological observations on the functional adaptations of the epidermic cells of insects, J. CHATIN (*Compt. Rend., 120 (1895), No. 4, pp. 213–215*).

Two new species of Lecanium from Brazil, T. D. A. COCKERELL (*Amer. Nat., 28 (1895), No. 2, pp. 174, 175*).—*L. reticulatum* and *L. baccharidis* are described as new.

The imported cabbage butterfly, A. N. CAUDELL (*Amer. Hort., 5 (1895), No. 2, pp. 22, 23, figs. 3*).—Popular life history and remedial notes, dusting with Paris green being recommended.

The cabbage plusia, A. N. CAUDELL (*Amer. Hort., 5 (1895), No. 2, p. 21, fig. 1*).—A brief popular descriptive note on *Plusia brassicæ*.

The turnip gall-weevil, S. HEATON (*Gard. Chron., 17 (1895), p. 398, fig. 1*).—A description of *Centorhynchus sulcicollis*. Gas lime at the rate of not more than 30 cwt. per acre is recommended as a preventive treatment.

A spring wheat pest, CLAUSEN (*Landw. Wochenbl. Schles. Holst., 45 (1895), No. 11, pp. 162, 163*).

A destructive caterpillar (*Ztschr. landw. Ver. Hessen, 1895, No. 9, pp. 68, 69*).—Notes are given on a silk-spinning caterpillar which has caused considerable damage to the leaves of *Helleboris niger*.

Injurious insects and fungi (*Jour. [British] Bd. Agr., 1 (1895), No. 3, pp. 300–316*).—Illustrated descriptions with suggestions for their repression are given for the woolly aphis and goat moth, and notes on horticultural legislation in British Columbia, cabbage root maggot in America, and wireworms.

Legislation against injurious insects, J. B. SMITH (*Ent. News, 6 (1895), No. 4, p. 122*).—Comments upon Bulletin 33 of the Division of Entomology, U. S. Department of Agriculture (E. S. R., 6, p. 916).

The inefficiency of Botrytis tenella in combating white grubs (*Rev. Scientif., 3 (1894), ser. 4, No. 14, p. 441*).—The author calls attention to the failure of *Botrytis tenella* for the repression of white grubs.

FOODS—ANIMAL PRODUCTION.

Investigations on pepsin digestion, F. KLUG (*Pflüger's Arch. Physiol., 60, No. 182, pp. 43–70*).—The author studied this subject with reference especially to the effect of the strength of the pepsin solution, the percentage of hydrochloric acid it contains, the duration of digestion, and the temperature. Pepsin prepared from the stomach of cattle, swine, and dogs was used, and the products of the digestion were investigated. His conclusions are as follows: (1) Of a number of extracts of a stomach lining made consecutively, the first is less powerful than the later ones. The activity of the first extract can be increased by diluting with water acidulated with hydrochloric acid, or by allowing it to stand for 24 hours before using. (2) For studies in artificial digestion cooked egg albumen is best fitted, but it must be borne in mind that this contains about 0.7 per cent of deutero-albumose. (3) Ammonium sulphate and common salt both retard pepsin digestion, the latter about 0.5 per cent. (4) The quantity of the pepsin in the digestive fluid, that is, the strength of the solution, is of marked effect on digestion. A solution containing 0.5 to 0.01 per cent of pepsin digests best, and the activity of the solution diminishes as it is stronger or weaker than this. Pepsin from the dog is most active in a 0.01 per cent solution, while that from pigs or cattle works best in a 0.1 per cent solution. (5) Pepsin digests best in the presence of 0.5 to 0.6 per cent of hydrochloric acid. Hence, a solution containing 0.1 per cent of pepsin and 0.6 per cent hydrochloric acid is the most advantageous. Twenty centimeters of such a solution will bring 6 gm. of hard cooked egg albumen into solution in 10 to 15 hours. (6) The digestion progresses rapidly during the first 10 to 15 hours, especially the first 4; after that it progresses very slowly; the formation of peptone and albumoses steadily increases, while by long continued digestion the syntonin gradually decreases. (7) In all the tests made syntonin and albumoses could be detected in the digestive solution within 5 minutes after the digestion had begun. (8) Where the pepsin from cattle and swine was used peptone did not appear until nearly 4 hours after commencing, while with dog pepsin it appeared in 20 to 40 minutes. (9) Since the pepsin from the dog surpasses that from cattle or pigs in activity, it is believed probable that there are different pepsins. (10) Digestion takes place at as low a temperature as 0° C. and increases with increasing temperature up to 50 to 60° C., above which it diminishes and ceases at 80° C. (176° F.). (11) Syntonin (precipitated by neutralizing) and the albumoses (obtained by ammonium sulphate) appear in the digestive solution simultaneously. (12) Syntonin does not occur as a result of the hydrochloric acid alone, but like the albumoses and peptone is a product of the united action of the hydrochloric acid and pepsin. (13) Ammonium sulphate and common salt both retard pepsin digestion, the latter about 0.5 per cent.

Comparing prairie hay with timothy hay, T. L. HÆCKER (*Minnesota Sta. Bul. 35, pp. 65–81*).—This comparison was made on 16 cows divided into 4 lots. These lots were fed grain with timothy hay or prairie hay in alternating periods, silage being added to the ration of 2 of the lots all the time. The grain consisted of a mixture of bran, ground barley, corn meal, and linseed meal.

"The prairie hay secured was fine in blade, of good quality, apparently early cut and not exposed to rain before stacking. It was almost free from swale grass and tall blue joint. The timothy hay was medium fine, rather short, cut early and properly cured, had a fine flavor, good color, and was first grade in every respect."

The analyses of the feeding stuffs used are tabulated, together with the record of the food consumed and milk and fat produced by each cow in the several lots.

In calculating the financial result prairie hay is valued at $3.20 and timothy hay at $5.60 per ton. The general summary of results is as follows:

"(1) As between early cut and well cured timothy hay and fine well cured upland prairie hay, cows preferred the prairie hay.

"(2) Prairie hay was at least equal to timothy for the production of milk and butter fat.

"(3) At the present price of the 2 kinds of hay, milk was produced at 13 per cent less cost and butter fat at 12 per cent less cost when prairie hay was fed."

Ensiling soja bean and vetch, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 109, 110*).—Soja bean and Russian or villous vetch were each grown on plats containing 2,500 sq. ft., and the green crops cut and ensiled, a part of the soja bean by itself and a part mixed with the vetch.

"After about 6 months the silos were opened and the contents fed out. The cows ate the silages readily, but the quantities were too small to admit of experimental feeding. Both silages kept nicely and had a pleasant aromatic odor."

The losses in ensiling are calculated. These amounted to 14 per cent of the dry matter in case of the soja bean and 25 per cent in case of the soja bean and vetch. The composition of the green material and the silage is given as follows:

Composition of green and ensiled soja bean and villous vetch.

	Moisture.	Composition of dry matter.							
		Crude ash.	Crude protein.	Crude fiber.	Nitrogen-free extract.	Ether extract.	Nitrogen.	Phosphoric acid.	Potash.
	Pr. ct.	*Pr. ct.*	*Pr. ct.*	*Pr. ct.*	*Pr. ct*	*Pr. ct.*	*Pr. ct.*	*Pr. ct.*	*Pr. ct.*
Soja bean, green fodder	75.36	12.16	20.29	22.53	41.56	3.46	3.24	0.709	1.775

Feeding test with various silages, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 70–81*).

Robertson mixture vs. corn silage (pp. 70–75).—The object of this trial was to compare the composition and the feeding value of silage made from a mixture of corn, horse beans (whole plant), and sunflower heads, as proposed by Prof. J. W. Robertson, of Canada, with silage made from corn alone. Two fifths of an acre of corn, one fifth of an acre of horse beans, and one tenth of an acre of sunflowers were planted for this purpose and cultivated as usual. All except the horse beans did well. Early in October this Robertson mixture was harvested and ensiled in one half of a silo, the other half being filled with ordinary corn. The silo was in poor repair, and the loss in ensiling was unusually large. It amounted to 33 per cent of the dry matter for the corn silage and 43 per cent for the mixed silage. Analyses are given of the materials as put in the silo and of both kinds of the good and spoiled silage. The following table shows the composition of the materials as put in and the silage taken out:

Composition of green and ensiled material.

	Water.	Composition of dry matter.							
		Crude ash.	Crude protein.	Crude fiber.	Nitrogen-free extract.	Ether extract.	Nitrogen.	Phosphoric acid.	Potash.
	Pr. ct.	*Pr. ct.*	*Pr. ct.*	*Pr. ct*	*Pr. ct.*	*Pr. ct.*	*Pr. ct*	*Pr. ct.*	*Pr. ct.*
Corn fodder as put in	77.21	5.42	7.59	23.26	59.49	4.24	1.21	0.430	1.509
Silage mixture as put in	74.91	5.87	10.53	21.36	56.07	6.17	1.68	.497	1.612
Corn silage as taken out	79.16	8.11	10.24	26.00	53.85	3.80	1.65	.470	1.921
Silage mixture as taken out	79.30	8.52	12.10	23.89	50.16	5.33	1.93	.717	2.376

"The effect of the horse beans and sunflower heads in the Robertson mixture is plainly shown in the protein and ether extract percentages.

The feeding value of these 2 kinds of silage was tested in a feeding trial with 5 cows, covering 4 periods of 3 weeks, which began December 24. The trial was rather unsatisfactory, as 2 of the cows were found to be tuberculous and were slaughtered, and the others were removed to an old barn, where they suffered much from the cold and were evidently affected by the changed conditions. The results of the trial are tabulated. Under the conditions prevailing "the mixture did not in these cases appear superior to corn silage in feeding value. We do not feel, however, justified in laying much stress on the results owing to the unfortunate complications."

Rye silage vs. corn silage (pp. 75–77).—Twelve cows were divided into 2 lots and fed during 2 periods of 4 weeks each on rye silage or corn silage, the lots being alternated on these. The cows received corn meal, wheat bran, and hay in addition to the silage. The composition of the corn and rye silage is given.

"The rye silage was much drier than the corn silage and was not relished as well. The cows were induced to eat all they would, yet left a good many orts, and ate but three quarters as much dry matter."

The results of the feeding are tabulated. Considerably more hay was eaten with the rye silage than with the corn silage. About 10 per cent less milk and butter was produced on the rye silage. There was a shrinkage of about 2 per cent in passing from corn silage to rye silage, and a gain of about 2 per cent in changing from rye to corn silage. The indications are that there was a loss of about one half from natural fermentation and fire fanging in ensiling of rye.

Corn and soja bean silage vs. corn silage (pp. 77–79).—Four rows of corn, equivalent to one fifth of an acre, with soja beans planted in the same rows, was harvested and ensiled separately; and for comparison an equal area of the same corn grown without soja beans. The composition of the materials as put in and of the 2 kinds of silage as taken out is given. The 2 kinds of silage were fed to 2 lots of 2 cows each in alternating 18-day periods.

"Both kinds of silage were well relished." . . .

"The milk was richer in both cases during the soja bean and corn silage feeding. This latter appears to be, practically, the only gain made by the addition of the soja bean to the corn.

"It would appear, then, that the addition of this small amount of soja bean plants to the corn in the silos did not materially improve the silage, or increase the milk or butter yields. Planting in the row with the corn was found to be better than planting in separate rows, because of greater economy of room and labor."

Pea and oat, and vetch and oat vs. corn silage (pp. 79–81).—The crops from 2 plats of oats and hairy vetch and 2 of oats and peas were harvested and ensiled together, no effort being made to keep the different kinds separate. This silage was fed out to the herd between October 7 and November 17. Analyses of the materials as put in the silo are given, together with a brief record of the herd while the silage was fed.

> "Nearly 7 lbs. more butter were produced by these 6 cows fed 6 weeks on pasture with ensiled oats, vetches, and peas than was made in the 6 weeks immediately preceding, on pasture, old silage, and fresh fodder corn, and nearly 40 lbs. more in the 6 weeks immediately following, when corn and rye silages were eaten.
>
> "It is not claimed that this is a strictly controlled experiment, but it serves to show that oats and vetch, and oats and peas, ensiled, may be expected to produce at least as good returns at the milk pail and in the churn as will corn silage."

Feeding trials with animals, F. E. EMERY (*North Carolina Sta. Bul. 109, pp. 419–449*).

The effect of cotton-seed hulls and meal as cattle food (pp. 419–424).—A discussion is given of the general character and feeding value of cotton-seed hulls and cotton-seed meal, and a review of the results obtained in a number of experiments, principally at the station, in feeding these materials in various combinations to steers and cows. From the experience at hand, rations containing these materials are suggested for fattening and for milk.

> "Where it is desirable to feed an animal just sufficient to maintain it without loss, the following rations may be used: Hulls from rather green seed may be fed alone, the particles of seed kernels remaining accidentally with the hulls being counted on for maintenance, or, perhaps, even for slow fattening. . . . With well cleaned hulls, however, some cotton-seed meal must be used, depending somewhat on the animal fed. . . . Probably 8 or 10 lbs. of hulls to 1 lb. of meal, when fed in quantity (as much as can be eaten clean), will support life and maintain the weight of neat stock.
>
> "For slow fattening rations ranging from 7 of hulls to 1 of meal down to 5 or 4 to 1 may be used, depending on the animals fed and skill of the feeder. . . .
>
> "Rations for making good beef quickly may range from 4 to 1 down to 2 to 1, or even 1.5 to 1, as we have fed steers successfully on the latter ration. . . .
>
> "When a cow has passed about 4 or 5 months of gestation, and the flow of milk has greatly diminished, she may be put on a ration of hulls and meal, which may be varied from 4 to 1 to as much as 7 or 8 to 1 of hulls to meal until she has dried off. This will support the cow well. It would be well all this time, however, to be feeding once per day some hay, stover, straw, or let her graze part of each day. For 2 or 3 weeks before calving, the cow's ration should be changed by substituting a succulent diet or bran for the cotton-seed meal."

Cotton-seed meal as a horse food (pp. 425, 426).—Two horses were fed in the first period a ration of clover straw (chaff), corn meal, and ship stuff, on which one horse gained and the other lost in weight. During the second period corn meal and ship stuff were both reduced 1 lb., and 2 lbs. of cotton-seed meal fed instead. During this period both horses gained in weight; there was "an almost regular advance in body weight." In the third period the cotton-seed meal was increased to 3½ lbs. and the clover straw was changed to timothy hay. Neither horse ate the timothy hay well and the period lasted only 8 days.

> "Neither horse showed any symptoms to indicate that the cotton-seed meal disagreed with it, but both objected to late-cut timothy hay after crimson clover straw and chaff. . . .
>
> "Later, in reply to an inquiry, Mr. E. d'Alinge, of the Biltmore estate, writes that he has for some time been feeding 2 lbs. per day, except Sundays, to work horses and mules. The ration, with cotton-seed meal in this case, being as follows: 13 to

15 lbs. cut hay and finely cut corn fodder, 4 lbs. wheat bran, 2 lbs. cotton-seed meal, 6 lbs. corn meal; the whole mixed together. On Sundays a change is allowed to whole grain, oats and corn, and uncut hay."

Cotton-seed meal for pigs (pp. 426, 427, 433–436).—Two pigs, weighing about 90 lbs. each, were fed the same ration, except that one received corn meal and the other an equal amount of cotton-seed meal.

"As the result of feeding cotton-seed meal, it may be stated that 4 oz. were fed per day with 32 oz. of wheat bran for 20 days, and 20 oz. per day of cotton-seed meal with 40 oz. of wheat bran for the following 21 days were fed and nearly all consumed by a hearty pig, without faltering; but when 2 lbs. per day were fed, the pig refused to eat so much, and became sick on what was eaten, but recovered on a corn diet. . . .

"Later a little more cotton-seed meal was fed, but, rather than risk the loss of the pig, it was dropped. After feeding a period on corn meal, both were slaughtered and comparisons of live and dressed weights were made. The pig which was fed on cotton-seed meal weighed 25 lbs. less than the other, and dressed 71.21 per cent of live weight. The pig fed on corn meal dressed 73.68 per cent of live weight."

Cotton-seed meal for calves (pp. 427, 436–439).—Three calves were fed skim milk to which one fourth to one half a pound of cotton-seed meal was added. After feeding a month or a month and a half all of the calves died.

"The death of one was due to licking up or eating sand. The other two are supposed to have been victims of some toxic agent in the cotton-seed meal which powerfully affects the nervous system. This apparently attacked three mature cows, probably causing the death of one."

Feeding skim milk to lambs (p. 428).—Ten lambs were fattened on skim milk with wheat bran, oats, corn, and green clover. All of the lambs were very wild. The tabulated financial result shows that "not only was nothing received for the separated milk which was fed, but there was a loss on the other food eaten."

A pig feeding test (pp. 428, 429, 440–447).—Four pigs, weighing from 75 to 100 lbs., were fed in 10-day periods to test 5 different rations composed of wheat bran, cowpea meal, and corn meal mixed in different proportions. The rations for all the pigs were the same except that the food for one was mixed with a little hot water and allowed to stand from one feeding to the next; for another was mixed to a thin slop; for a third was mixed with cold water, and for a fourth fed dry. Skim milk or buttermilk was added to the food. The results of the trial are fully tabulated.

"The addition of sufficient cold water to the grain to make the ration sloppy gave the poorest result in gain, while the dry food gave the best result.

"As to the result of the feeding, the gain in weight paid for the value of the grain fed, and paid also for the separated milk for the 50 days' feeding, from 1.4 cts. to 2.03 cts. per gallon. During the last 50 days there was not enough gain in live weight to pay for the grain fed, and consequently nothing was received for the milk."

A system of feeding young calves (pp. 429, 430, 448, 449).—Receipts are given for foods used at the station for young calves in changing from cows' milk to skim milk. These consisted for the most part of whole milk, skim milk, and linseed meal in different proportions.

Fattening mature steers on cotton seed and cowpea hay, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Bul. 31, pp. 3–11*).—Two half-grade 3-year-old steers were fed in box stalls for 90 days, beginning January 23. Both received whole cotton seed and cowpea hay, the amount being 13.6 lbs. of seed and 20 lbs. of hay per steer. The steers gained 270 lbs. and 274 lbs., respectively. They were bought at 2 cts. per pound and were estimated to be worth 3½ cts. at the close of the trial. With cowpea hay at $3 per ton and cotton-seed meal at $5, there was a profit of $21.30 for the 2 steers.

"Two small 1½-year-old steers were fed for 35 days in the experiment in exact manner of the 2 large steers. They showed no bad effects whatever from the seed, and made a daily average gain of 3.1 lbs."

Raising dairy bred calves, T. L. HÆCKER (*Minnesota Sta. Bul. 35, pp. 82–92, fig. 1*).—This experiment was made to compare the cost of raising calves on whole milk, and on skim milk supplemented by flaxseed meal, and to note the effects of these 2 rations on the thriftiness of the calves. Nine calves were used, 1 being fed on whole milk during a period of 60 days, while 8 were gradually changed to skim milk and flaxseed meal. The time covered by the trial varied from 12 to 24 weeks with the different calves. The food eaten, gain in weight, and cost of the food per pound of gain are tabulated for each animal, and an analysis is given of the flaxseed meal. The following table gives a general summary of the results:

Summary of feeding experiments with calves.

	Length of trial.	Cost of food.	Weight at end of trial.	Gain in live weight.		Cost of food per pound of gain.
				Total.	Average per day.	
	Days.		*Pounds.*	*Pounds.*	*Pounds.*	*Cents.*
Calf No. 1, whole milk diet	61	$13.88	245	160	1.90	9.69
Calf No. 2, skim milk diet	84	3.48	160	100	1.19	3.49
Calf No. 3, skim milk diet	140	5.07	234	179	1.28	2.88
Calf No. 4, skim milk diet	140	4.82	205	133	.95	3.84
Calf No. 5, skim milk diet	140	5.10	235	150	1.07	3.51
Calf No. 6, skim milk diet	168	6.58	257	192	1.14	3.47
Calf No. 7, skim milk diet	168	7.32	420	338	2.01	2.40
Calf No. 8, skim milk diet	168	5.33	270	210	1.25	2.54
Calf No. 9, skim milk diet	168	6.55	265	193	1.14	3.71
Average for calves fed on skim milk	....	....	....	....	1.25	3.23

"While the experiment was fairly satisfactory as to the general growth of the calves, the details in feeding were not as carefully carried out as the importance of the work required. It is therefore being repeated with a view of obtaining more accurate data, though it can hardly be expected that our efforts will result in growing a finer lot of calves."

Effect of weather on the quantity and quality of milk, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 88–92*).—Observations on this subject have previously been reported by this station in the Annual Reports for 1891 and 1892 (E. S. R., 4, p. 491; and 5, p. 322). In addition to these tests observations are here reported on two other tests. The first of these was with 17 cows and extended from September 15 to early in November. The cows were at pasture but were stabled during the night. The cows were grouped according to the quality of their milk, and samples of the morning's and night's milk of each group were tested daily with the Babcock test and lactometer. Opportunity was afforded for 72 comparisons of the effect of changes of temperature on percentages of total solids and fat in the milk.

"In cases of general rising quality no connection with weather could be traced. The amount of change was as great one way as another.

"During stationary temperatures, more or less quality fluctuations occurred, but they were found to be equally divided in direction.

"In brief, it may be said that more than half (55 per cent) of the changes in fat percentage, and nearly two thirds (65 per cent) of the changes in per cents of total solids were opposite to those of the thermometer, but that for periods of more than a day the inverse character of the quality change was less marked.

"Coincident with a warm spell [October 15 to 25] the milk flow fell for the first time below the line of calculated natural shrinkage. On the other hand, 5 days averaging as warm (October 3 to 7) were accompanied with a little more milk than usual. There was a marked decrease in quantity early in November, as the weather grew colder."

The other test was with 7 cows stabled in a poorly constructed barn on a bleak hillside, and lasted from February 25 to March 30, 1894. The morning's and night's milk of each cow was tested by the Babcock test. Omitting the times when the temperature varied less than 5° from day to day, there were 40 opportunities for observing the effect of changes of temperature on the milk.

"These show that 21 times the quality change was inverse to temperature change, 13 times in the same direction, and 6 times no quality change followed thermometric fluctuation. Nearly two thirds (62 per cent) of the changes were in the inverse direction to temperature change. They were also more pronounced than the changes in the same direction (0.275 per cent inverse, 0.215 per cent same).

"There were 12 cases of rather decided temperature changes extending over 3 days or more (using both sets of temperatures separately). The general quality of the milk changed inversely 6 times, in the same direction twice, and fluctuated irregularly 4 times. Three quarters of these changes were in the inverse direction."

From a study of the records of the World's Fair test the statement is made that "over half the changes in per cent of total solids, and three quarters of the changes in fat percentages were inverse to thermometric variations. . . . No connection could be traced between temperature and quantity changes (save as high temperature induced lighter feeding and consequent falling off) or between storm, and either quantity or quality change."

The author summarizes the results of the 2 tests previously reported, and taking these in connection with those reported above, draws the following inference:

"These 5 separate tests, covering practically the entire year, and the conditions of pasture, summer soiling, and winter barn feeding, point directly to the conclusion that the tendency of cows is to give from day to day richer milk when the temperature falls and poorer milk as it rises; or, in other words, the quality of the milk (solids and fat) varies inversely to temperature changes."

Cost of butter production in winter, T. L. HÆCKER (*Minnesota Sta. Bul. 35, pp. 54–64, figs. 5*).—In connection with the observations on the herd of 23 cows (p. 928), the cost of producing butter in winter was determined for each cow. The cost of the feed was calculated on the same basis as in the yearly record. Each milking was weighed and tested by the Babcock test and the cows were weighed weekly.

> "It was found impossible to make the trial the same length for each cow for the reason that they were not all at the same time in a condition which would make it fair, so each cow was placed on trial at a time when it was thought she would do herself justice."

The trial with different cows lasted between 112 and 181 days. The data given include the average live weight of the cows, the dry matter eaten per day per 1,000 lbs. live weight and per pound of butter fat produced, the butter fat produced per day, and the cost of food per pound of butter fat. These all show very wide variations, the dry matter eaten per 1,000 lbs. live weight varying from 14.60 to 28.24 lbs., the dry matter eaten per pound of butter fat from 18.44 to 31.05 lbs., and the cost of food per pound of butter fat from 10.8 to 17.8 cts.

> "It is evident that some cows produce butter fat much cheaper than others, the variation being so great that under certain conditions one class will produce it at a profit and another at a loss."

The author concludes that it is not a question of the size or breed of the cow, but rather of conformation; and he divides the herd into 4 groups on this basis as follows: (1) Beefy cows, (2) those with less tendency to plumpness, (3) cows spare and angular in form but lacking depth, and (4) cows spare and angular with deep bodies. For each of the cows in these different groups the weight is given, the dry matter eaten per 1,000 lbs. and per pound of butter fat, and the cost of food per pound of butter fat, together with the average for each group. The range of variation and the averages are given in the following table:

Record of butter production by groups.

Groups.	Dry matter eaten daily per 1,000 lbs. live weight.			Dry matter eaten per pound of butter fat.			Cost of food per pound of butter fat.		
	Highest.	Lowest.	Average.	Highest.	Lowest.	Average.	Highest.	Lowest.	Average.
	Lbs.	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Cts.*	*Cts.*	*Cts.*
1. Beef type, blocky and plump	19.96	14.61	16.66	32.47	28.94	31.25	18.2	16.4	17.5
2. Less tendency to lay on flesh	25.15	16.75	21.02	31.05	24.44	26.42	17.8	13.8	15.1
3. Spare and angular, but lacking depth.	23.59	22.09	23.00	28.58	23.75	25.54	16.6	13.4	14.6
4. Spare and angular with deep bodies.	28.24	17.87	23.58	23.06	18.44	21.15	12.9	10.8	12.1

These figures show a steady increase from group 1 to group 4 in respect to the amount of dry matter eaten per 1,000 lbs. live weight, but a decrease in the dry matter eaten per pound of butter fat produced and in the cost of food per pound of butter fat.

"The cost of butter fat as indicated in the last column seems to depend more upon the type of cow than the breed, there being less variation in cost of production between cows of a certain type than between cows of the same breed. The cost of 100 lbs. of dry matter was 57 cts. . . .

"The first group consumed, on an average, 20.81 lbs. dry matter per day, returning 4.7 cts. profit [with butter fat at 25 cts. per pound]; the cows in group 2 ate 20.37 lbs. dry matter and gave 7.5 cts. profit; group 3 ate 19.95 lbs. each and returned 8.1 cts., while group 4 ate 21.86 lbs. each per day at a profit of 13.3 cts., or nearly 3 times as great a net profit as the blocky cows in group 1."

The effect of feeding bone meal on the character of the milk, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 106, 107*).—To observe the effect of feeding bone meal on the ash and phosphoric acid content of milk, 2 Ayrshire cows were fed 2 lbs. each per day of clean ground bone. The milk was tested for ash and phosphoric acid a number of days before adding the bone meal, and for 10 days after the cows had become accustomed to it. The average results for each cow are given in the following table:

Ash and phosphoric acid in milk before and after feeding bone meal.

	Cow Hilda.		Cow Juno.	
	Ash.	Phosphoric acid.	Ash.	Phosphoric acid.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Before feeding bone meal	0.802	0.2142	0.702	0.1809
After feeding bone meal	.809	.2263	.704	.1919
Gain on bone meal	.007	.0121	.002	.0110

"There appeared little difference in the percentage of ash, but its composition seems to have been slightly changed and the phosphoric acid increased."

Effect of the change from barn to pasture, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 107–109*).—Previous observations on this subject have been reported in the Annual Reports of the station for 1889, 1890, 1891, and 1892 (E. S. R., 2, p. 667; 3, p. 477; 4, p. 491; and 5, p. 317). The present observations were on the new station herd of 21 cows. They ate before and after the change a liberal ration of equal parts of corn meal and bran, with hay and silage, and were stabled at night during the pasture period. The milk was tested for 20 days previous to pasture and for the same length of time beginning 10 days after the change. The changes in the milk yield and constituents of each cow in changing from barn to pasture are noted.

"The cows gained in both quantity and quality of the milk, and made more butter on pasture. Out of 21 cows but 2 failed to increase in the milk flow and but 2 lowered its quality as a result of the change.

"The average gain was equivalent to nearly 3 lbs. of milk and nearly a quarter of a pound of butter per day and per cow, while the fat was increased over a third per cent. The quality of milk was increased a seventh, and because of the increase in both the quantity and the quality of the milk, the butter yield was increased nearly a quarter."

The changes noted in the observations previously reported are summarized.

"The evidence appears overwhelming that cows on early pasturage—May and June—make not only more but richer milk than during the last months of their barn life."

Whale flesh meal as a food for milch cows, J. SEBELIEN (*Aas, Norway: 1894, pp. 33*).—A feeding experiment with 20 cows was conducted at Aas Agricultural College to trace the effect of whale flesh meal on milk and butter production. The experiment included 3 main periods, (1) the preparatory period, lasting 32 days; (2) the experimental period proper, lasting 50 days; and (3) the post-experimental period, lasting 20 days. The cows were separated into 2 even lots of 10 each. During the first and third periods both lots were fed a basal ration of 80 kg. of turnips, 90 kg. of cut straw, 40 kg. of hay, 10 kg. each of rape-seed meal, linseed meal, and malt sprouts. Lot A received this ration during the second period also, the quantities fed being somewhat changed; but lot B received 0.5 kg. of flesh meal per head per day during the first 20 days of the second period in addition to the ration in the first period, and later from ½ to 1½ kg. of the concentrated feed in the ration was replaced by a like quantity of flesh meal. The following table gives the average results obtained:

Average daily production of milk and fat per cow.

	Lot A, same feed throughout.			Lot B, whale flesh meal during period 2.		
	Yield of milk.	Fat content.	Yield of fat.	Yield of milk.	Fat content.	Yield of fat.
	Pounds.	*Per cent.*	*Pounds.*	*Pounds.*	*Per cent.*	*Pounds.*
First period	20.08	3.35	0.674	20.13	3.51	0.705
Second period	17.77	3.40	.604	17.97	3.67	.658
Third period	15.67	3.57	.560	15.94	3.64	.580

It would appear that the feeding of flesh meal increased the production of milk and slightly improved its quality. The author concludes that this result will be obtained whether the flesh meal be fed in addition to an ordinary fairly rich ration, or in partial substitution of the vegetable concentrated feeds in the same. If the ration is rather scant and of a narrow nutritive ratio, the addition or substitution of whale flesh meal will produce no increase in the yield of fat, since the milk under such conditions seems to grow thinner, even if the milk yield is increased.

The average live weights of the 2 lots of cows remained nearly unchanged throughout the experiment.

Neither the quality nor the flavor of the butter was apparently affected by feeding as much as 3.3 lbs. of flesh meal per head per day. In a record given of the experience of practical farmers in feeding flesh meal to milch cows, it is stated, however, in one instance that while butter from flesh meal feeding will be faultless when first made, a fishy taste is apt to appear when the butter is kept for some time. The consensus of opinion among farmers is on the whole favorable to the use of whale flesh meal for cows. The quantities fed ranged from 0.4 to 3.3 lbs. per head per day. Flesh meal is also reported as fed to bulls, growing cattle, swine, and poultry with satisfactory results.—F. W. WOLL.

Dairy herd record for 1893, T. L. HÆCKER (*Minnesota Sta. Bul. 35, pp. 37–53, fig. 1*).—This is a record for the year 1893 of the 23 cows of the college herd, including the kinds, amount, and cost of food eaten; weight of cows and milk and butter fat produced; percentage of fat in milk; and cost of feed. The herd included the following breeds: Jersey, Holstein, Guernsey, Shorthorn, Polled Angus, and crosses and grades of these breeds. The data are given for each of the cows individually.

"No special effort was made to select an economical ration; the cows were fed bran, barley, corn, linseed meal, silage, roots and hay as had been the practice theretofore."

The milk from each milking was weighed and recorded and a sample taken for testing. The data given are discussed in detail.

"The record of the dairy herd for the year 1893 seems to warrant the following conclusions:

"(1) The average annual cost of keeping a dairy cow is $38.

"(2) A herd of cows bred on dairy lines, well fed and carefully handled, will produce on an average 6,400 lbs. of milk per year at a cost of 62 cts. per 100 lbs. and 12½ cents a pound for butter fat.

"(3) A herd of good dairy cows well fed and carefully handled will produce on an average 300 lbs. of butter fat each per year, which is equivalent to 365 lbs. of butter per cow.

"(4) The average cost of a pound of butter will be 10½ cts.

"(5) Taking the entire herd, the average cost of a pound of butter fat during the winter months is 13.9 cts."

Records of the station herd for 1892 and 1893, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 81–87*).—This is a detailed record for each cow of the station herd for the years 1892 and 1893. The record for 1892 is reprinted with some additions from the Annual Report of the station for 1892 (E. S. R., 5, p. 320).

The record for 1893 includes 21 cows. It shows the number of days the cows were in milk, the total yield and composition of the milk of each cow, the yield of milk constituents, the calculated yields of butter and cheese, the number of pounds of milk required to make 1 lb. of butter and cheese, and the relation between the value of the entire product from butter and cheese. The butter yield is calculated by assuming 110 lbs. of butter to be made from 100 lbs. of butter fat, and the yield of green cheese is calculated by multiplying the per cent of fat by 1.1 and the per cent of casein by 2.5. The summary of the record for 1893 is as follows:

Average per cow for the year 1893.

	Total yield of milk.	Composition of milk.		Yield of milk constituents.			Calculated yield of—		Milk required per pound of—	
		Total solids.	Fat.	Total solids.	Fat.	Casein.	Butter.	Cheese.	Butter.	Cheese.
	Lbs.	*Per ct.*	*Per ct.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*
Average per cow	6,455	13.68	4.38	883	283	182.0	311	758	20.8	8.5
Average 6 mature Jerseys	6,232	14.73	5.22	918	325	198.2	358	853	17.4	7.3
Average 1 mature Aryshire	8,273	12.31	3.57	1,018	295	194.1	325	811	25.4	10.2
Average 4 Holsteins	8,420	12.80	3.73	1,078	314	208.0	345	865	24.4	9.7
Average 3 best Jerseys	7,197	14.66	5.21	1,055	376	228.9	413	986	17.4	7.3

The yield of the herds for 1892 and 1893 as regards quantity and quality of milk are compared, and the composition of the milk of a number of young cows for the first 2 periods of lactation is compared.

"The regular members of the station herd of 1892 averaged 7,197 lbs. of milk and 351 lbs. of butter, while in 1893 the regular members averaged 7,115 lbs. of milk and 341 lbs. of butter. The entire herd made during the same years 147,609 and 135,615 lbs. of milk and 7,014 and 6,541 lbs. of butter.

"Calculations based on Dr. Van Slyke's work indicate that the regular members averaged 856 and 831 lbs. of cheese, and the entire herd produced milk equivalent to 17,154 and 15,926 lbs. of cheese in 1892 and in 1893, respectively. The poorer record for 1893 was partly due to abortion. There was no material change in the quality of the herd milk for the 2 years and but slight variations in the quality of the milk of the individual cows. The 2-year-olds of 1892 gave the same or slightly better quality of milk during their second lactation. The milk, except that of 2 Jerseys, was found to be worth as much for cheese as for butter, at the average market prices. . . .

"If 2½ lbs. of cheese are considered to be equal in market value to a pound of butter, which are fair market conditions, then for every $100 obtained for the herd milk made into butter there would have been received $98 if the milk had been made into cheese."

Pig feeding, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 30–40*).

Synopsis.—An experiment on 2 lots of pigs of the effect of feeding bulky as compared with more concentrated food during the early growth of the pigs on the general gain in weight, and on the shrinkage of the pigs in dressing. The difference in richness of the rations was brought about by feeding more or less corn meal in proportion to the skim milk. Those on the narrower rations gained faster and ate less dry matter per pound of gain than those on the wider rations, but the shrinkage on dressing was the same with both lots. At current prices the skim milk fed to the pigs was calculated to have brought about 25 cts. per 100 lbs.

Four Chester Whites and 4 Small Yorkshires were selected for the experiment when about 8 weeks old, and divided into 2 lots with 2 pigs of each breed in each lot. After feeding both lots alike for about 3 weeks the experiment was commenced May 30 and continued until December 10 with the Chester Whites and until January 10 with the Small Yorkshires. Lot 1 (bulkier food) received 2 oz. of corn meal per quart of skim milk until they were taking 6 qt. of skim milk, when the additional food required consisted of a mixture of equal parts of corn meal and wheat bran until they weighed 200 lbs., when they were finished off on skim milk and corn meal. Lot 2 was fed on skim milk alone until they took 9 qt. per day, when an ounce of corn meal per quart of skim milk was added until 12 qt. was being taken, when the corn meal was doubled until the pigs weighed 150 lbs. each; they were then given all they would eat of the corn meal and wheat bran mixed, and were finished off in the same manner as lot 1. Soon after the beginning of the experiment the 2 Small Yorkshires in lot 1 died.

The data for the experiment, including the gains in live weight by periods, the amounts of food and of dry matter eaten, financial results, and the loss on dressing, are tabulated. The financial results are based on dressed pork at 7 cts. per pound, corn meal at $21 and bran at $17 per ton, and skim milk at 15 cts. per 100 lbs.

A summary is given in the following table:

Summary of results of pig feeding trial.

Lot.		Average gain in live weight.	Shrinkage in dressing.	Dry matter eaten. Per lb. gain in live weight.	Dry matter eaten. Per lb. gain in dressed weight.	Cost of food per pound of gain in dressed weight.	Average profit per pig.
		Pounds.	*Per cent.*	*Pounds.*	*Pounds.*	*Cents.*	
1	Chester Whites, bulkier food......	264	13½	3.24	3.73	4.83	$4.84
2	Chester Whites, narrower ration .	290	13⅛	3.17	3.64	5.05	5.09
2	Small Yorkshires, narrower ration	211	16	3.33	3.96	5.58	2.62

"The Chester Whites of lot 2, whose ration was narrower than those of lot 1—

"(1) Gained faster,

"(2) Reached a greater live weight,

"(3) Shrank the same, and

"(4) Ate less dry matter to make a pound of live or dressed weight than did the pigs whose food from the beginning was bulkier. Chester White No. 2 of lot 2, however, weighed no more at slaughter than did the Chester Whites of lot 1, notwithstanding it had eaten 75 lbs. more dry matter. This makes the cost of the food of this pig so high and so reduces the profits that the total profit per pig for the 2 lots is nearly the same. . . .

"The Small Yorkshires grew slowly. . . . They gained less in more time, ate more dry matter to the pound of gain in live or dressed weight, and their food cost more per pound of increase of dressed weight than that fed the Chester Whites. . . . They were kept at a profit, yet the money gain from 7½ months of feeding was but little more than one half that derived from a month's less feeding with the larger breed. . . .

"If the manure is considered to offset the care and the cost of gain is subtracted from the price obtained for dressed pork, the skim milk may be considered to have brought 25 cts. per 100 lbs. The fertilizing value of the food was 58 per cent of its market value."

Proper amount of skim milk for finishing off (p. 37).—From October 11 to December 10 lot 1 received 366 qt. of skim milk and 374 lbs. of corn meal each, and the Chester Whites in lot 2 received 732 qt. of skim milk and 339 lbs. of corn meal each.

"The pigs that ate the most gained the most, but . . . the extra 23 lbs. live weight cost $1.93 more, or 8.4 cts. per pound, whereas it only brought 7 cts. This is a reversal of the results found with 8 pigs last year [E. S. R., 5, p. 318], but, as before stated, pig 3 [in lot 2] did so poorly that he lowered the average and the results are less satisfactory than might be wished."

Pig feeding, L. FOSTER (*Montana Sta. Bul. 3, pp. 35–62*).—This is a popular bulletin discussing the principles of feeding, the average composition of American feeding stuffs, feeding standards, and preparation of food, together with quotations from the work of some of the stations in feeding pigs.

Analyses of milling by-products, J. L. HILLS and B. O. WHITE (*Vermont Sta. Rpt. 1893, pp. 26–28*).—Analyses with reference to food constituents and notes on methods of manufacture are reported for the following materials: Corn oil cake, gluten meal, gluten feed, scorched barley, maize feed, middlings, ground peas and oats, oat hulls, "nutriotone," and peanut meal.

What constituents of wine hinder pepsin digestion? H. PETERS (*Ber. pharm. Ges., 4 (1894), p. 258; abs. in Chem. Ztg., 18 (1894), No. 102, Repert., p. 329*).

Comparative examinations of different meat extracts, A. STUTZER (*Ztschr. angew. Chem., 1895, No. 6, pp. 157, 158*).

Cocoa as a food material, H. COHN (*Ztschr. physiol. Chem., 20, No. 1 and 2, pp. 1–27*).—An extended study of the food nutrients of cocoa and their digestibility as shown by the natural and artificial methods. Artificial digestion showed 64 per cent of the nitrogen digestible, including the theobromin. In a digestion trial on the author himself 52.7 per cent of the protein and 95.38 per cent of the fat were digested.

On roasted chicory, E. G. CLAYTON (*Analyst, 20 (1895), Jan., pp. 12–15*).

Heat production in the chick before and after hatching, M. S. PEMBREY, M. H. GORDON, and R. WARREN (*Jour. Physiol., 17 (1894), pp. 331–348; abs. in Jour. Chem. Soc. London (1895), Feb., p. 51*).

On the nature of muscular contraction, T. W. ENGLEMANN (*Nature, 51 (1895), Mar. 28, pp. 519–524, figs. 2*).

Sugar in the nutrition of animals, A. VIVIEN (*Ind. Lait., 20 (1895), No. 13, pp. 99, 100*).

The feeding of animals for the production of meat, milk, and manure and for the exercise of force, LAWES and GILBERT (*Jour. Roy. Agl. Soc. England, 6 (1895), No. 21, pp. 47–146, tables 2*).—The substance of this article will be contained in a bulletin on the Rothamsted Station soon to be issued by this Department.

Compounding rations for animals, P. FAUCOMPRÉ (*Ind. Lait , 19 (1894), No. 48, pp. 382, 383*).

Feeding milk cows with hairy vetch, C. J. MARTIN (*Ind. Lait., 20 (1895), No. 3, pp. 19, 20*).

The influence of the month of calving on the milk production of a cow, P. SCHUPLI (*Einfluss der Kalbezeit der Kühe auf die Milcherzeugung und auf die Aufzucht. Berlin: Pub. by Molkerei Zeitung, 1894; abs. in Fühling's landw. Ztg., 44 (1895), No. 4, pp. 75–80*).

Peanut oil as a substitute for milk fat in calf feeding (*Landw. Wochenbl. Schles. Holst., 45 (1895), No. 11, pp. 167–169*).

Measurements of hogs of different breeds, JUNGHANNS (*Mitt. deut. landw. Ges., 1895, No. 5, p. 52, fig. 1*).

Heredity in horses, A. OLIVER (*Bul. Min. Agr. France, 13 (1894), No. 8, pp. 892–907*).

Barnyard fowls R. SAINT-LOUP (*Les oiseaux de basse-cour. Paris: J. B. Baillière et fils, pp. 369, figs. 107*).

Characteristics of breeds of chickens, E. LEMAINE (*Agl. Gaz. N. S. Wales, 5 (1894), No. 12, pp. 878–880*).—A tabulated summary giving number of eggs laid, daily increase in weight of chick, weight when 6 months old, and other data for 33 breeds.

VETERINARY SCIENCE AND PRACTICE.

Glanders, W. L. WILLIAMS (*Montana Sta. Bul. 4, pp. 67–113, pls. 7*).—This is a general discussion on the subject in popular form. Among the topics treated are the pathology, symptoms, and diagnosis of glanders; strangles, pink eye, acute nasal catarrh, infectious or epizootic catarrhal fever, chronic nasal catarrh, diseases of the facial sinuses, diseased teeth, and nostril tumors, which have sometimes been confused with glanders. The only safe method of diagnosis is the use of mallein.

> "Although most modern investigators admit the curability of some cases of glanders, these recoveries are confessedly few and the treatment of the malady, whether by medicines or mallein, is yet purely experimental, unworthy of confidence from a practical standpoint, yet pointing hopefully toward reliable treatment in the near future. Apparent recoveries from glanders are unfortunately too often apparent only, and serve to continue the spread of the disease."

Experimental trichinosis in Spermophilus 13-lineatus, C. W. STILES (*Vet. Mag., 1894, pp. 727, 728; Centbl. Bakt. und Par., 16 (1894), No. 19, pp. 777, 778*).—The disease trichinosis was given experimentally to spermophiles, but the author does not believe that these animals are of any practical importance in transmitting the disease to hogs.—C. W. STILES.

Discussion of the coccidian origin of cancer, FABRE-DOMERGUE (*Ann. Micrographie, 1892, pp. 49–67, 97–110, 145–164, 221–236, 579–587, 603–614, figs. 27*).—The author's conclusions may be summarized as follows: (1) The parasite theory of cancer, originating in the writings of Pfeiffer, Darier, Wickham, and d'Albarran, rests upon observations which have no connection with one another and no analogy; (2) the objects described as *Sporozoa* have only certain morphological resemblances to these animals, but do not possess coccidian characters; (3) all the pseudococcidia as yet described are connected by insensible gradations with the neoplastic cell, from which they originate by degeneration; (4) epithelial cancers of animals, really homologous to those of man, are also not parasitic; (5) in attempting to demonstrate the necessity of a parasitic origin by comparing epithelial cancers with galls of vegetables and infectious neoplasms of animals one fails to recognize the very nature or essence of cancer and compares conditions which are not comparable.—C. W. STILES.

Notes on parasites, C. W. STILES and A. HASSALL (*Vet. Mag., 1894, pp. 729–741, figs. 11*).—*A new species of intestinal fluke* (*Distomum tricolor*) in the cotton-tail rabbit (*Lepus sylvaticus* Bachman) and in the Northern hare (*L. americanus* Erxleben). This species is found to be common in Maryland, the District of Columbia, and Virginia; it stands midway between the genera *Mesogonimus* and *Urogonimus*, and the authors are doubtful as to the validity of these two genera.

Distomum* (*Polyorchis*) *molle (Leidy, 1856, S. and H., 1894).—Anatomical description of original types of *Monostomum molle* Leidy.—C. W. STILES.

New American finds of Sarcosporidia, C. W. STILES (*Vet. Mag., 1894, pp. 928, 929*).—An undescribed species of *Miescheria* is present in the heart of nearly all cattle examined in the District of Columbia; an undescribed species has been found in rabbits in Illinois by Schimer and in Maryland by Hassall; *Sarcosporidia* were found very common in Iowa rats by Stiles; *Balbiaria* sp. found in *Setophaga ruticilla* by Hassall; an undescribed Sarcosporidium found in chickens by Stiles.—C. W. STILES.

On the genus Gongylonema Molin, L. G. NEUMANN (*Mem. Soc. Zool. France, VII, pp. 463–473, figs. 4*).—A general revision of the genus *Gongylonema* (family *Filariidæ*) based upon material from Africa and India. Revised generic and specific diagnoses are given. The following synonymy and data are given for the forms which occur in domesticated animals:

(1) *G. scutatum* (Müller, 1869) Railliet, 1892 (*Spiroptera scutata œsophagea bovis* Müller, 1869; *Filaria* sev. sp. *scutata* Lkt., 1876; *Myzomimus scutatus* Stiles, 1892) recently found by Fayet in 105 out of 136 cattle examined at Tébessa (Algeria); the parasite occurred in nearly every animal infested, in the thoracic portion of the œsophagus. Fayet found the same thread worm in 14 per cent of 494 sheep examined at Tébessa, and Boulant found it in nearly all the sheep slaughtered at Sétif. Fayet also found it in (34=) 32 per cent of the goats examined. It has also been found in the horse (Müller).

(2) *G. pulchrum* Molin, 1857, was found by Fayet in the œsophogeal epithelium of 5 out of 20 hogs.

(3) *G. verrucosum* (Giles, 1892) Neumann, 1894 (sp. *verrucosa* Giles, 1892; *G. scutatum* Railliet, 1894, ex parte), which Railliet believed was identical with *G. scutatum*, is reëstablished as a distinct species. It was found by Giles in India in the epithelium of the stomach of sheep and of the zebu.

The other forms mentioned are *G. musculi* (Rud., 1819) from the mouse (*Mus musculus*); *G. filiforme* Molin, 1857, from *Inuus ecaudatus; G. spirale* Molin, 1857, from *Cervus dama;* and *G. ursi* (Rudolphi, 1819) from *Ursus arctos.*

Neumann's original observations are confined to the species from domesticated animals.—C. W. STILES.

A bibliography, history, etc., of Italian helminthology, C. PARONA (*Atti R. Univ. Genova, 13 (1894), pp. 733, map 1*).—This elaborate work by Parona is divided into four parts: (1) The history of helminthology in Italy; (2) the parasites treated systematically, with cross references to the literature under each group, and a compendium of species arranged according to their hosts; (3) the geographical distribution of the various parasites in Italy; and (4) an almost complete bibliography of Italian works on helminthology, a short abstract of each paper being given. The map gives the geographical distribution of the parasites of man in Italy.

This work represents years of hard labor on the part of Parona, and is one which is absolutely indispensable to all original workers in helminthology.—C. W. STILES.

A test of serum from tuberculous animals as a diagnostic agent for tuberculosis, EBER (*Ztschr. Fleisch- und Milch Hyg., 5 (1895), No. 5, pp. 91, 92*).—No reaction resulted after the serum was employed.

The teeth of the horse, W. G. RIDEWOOD (*Nat. Sci., 6 (1895), No. 38, pp. 249–258, figs. 2*).

DAIRYING.

The composition and analysis of milk and milk products, H. D. RICHMOND (*Analyst, 20 (1895), Mar., pp. 54–56*).—A report on the work done during 1894 in the laboratory of the Aylesbury Dairy Company. The results of analyses of 28,455 samples of milk are summarized by months. The average for the year was 1.0322 sp. gr., 12.67 per cent solids, 3.86 per cent fat, and 8.81 per cent solids-not-fat. "As is usual, the poorest milk is found in the summer and the maximum is attained in November."

The 2,269 samples of cream tested showed an average for the year of 48.9 per cent of fat. The average for 44 samples of clotted cream was: Water 31.59, fat 60.25, solids-not-fat 8.16, and ash 0.69 per cent.

The composition of the 174 samples of butter from different countries was as follows:

Composition of butter as sold in England.

	Water.	Fat.	Solids-not-fat.	Salt.	Ratio of water to solids-not-fat less salt.
French butter, fresh (41 samples):	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	
Highest	14.32	86.08	2.47	0.19	....
Lowest	12.78	84.19	.78	.03	....
Average	13.60	85.05	1.35	.09	9.2
French butter, salted (31 samples):					
Highest	13.57	87.72	4.63	3.29	....
Lowest	9.68	82.98	1.96	.57	....
Average	11.27	85.28	3.45	1.97	13.1
Brittany butter (6 samples):					
Highest	14.81	84.36	2.01	.25	....
Lowest	13.75	83.18	1.78	.09	....
Average	14.26	83.84	1.90	.16	12.2
English butter, fresh (22 samples):					
Highest	15.23	87.62	1.83	1.07	....
Lowest	11.90	84.03	.48	.01	....
Average	13.49	85.70	.81	.14	5.0
English butter, salted (46 samples):					
Highest	16.39	87.65	5.16	4.30	....
Lowest	10.19	79.99	1.90	.90	....
Average	13.11	83.94	2.95	2.11	6.4
Australian and New Zealand butter (6 samples):					
Highest	12.53	89.82	2.59	1.55	....
Lowest	8.24	85.41	1.44	.92	....
Average	10.72	87.21	2.07	1.23	7.9

The analysis is given of the fat of several samples. Analysis of a sample of salted butter when first made and after keeping in a cask for 1 month showed that the percentage of water had diminished from 15.24

when fresh to 11.08, and the salt from 3.96 to 2.61, the conclusion being that the water had run out rather than evaporated.

A contribution to the study of the ash of cheese, G. MARIANI and E. TASSELLI (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 23–26*).—Analyses of the ash of 15 samples of cheese made by different methods are tabulated. The ash of 2 samples gave slightly alkaline reaction, that of all other samples being neutral.

In all samples there was less lime than phosphoric acid, the percentage of phosphoric acid being from 1.07 to 1.75 times that of the lime.

Edam cheese with 77.984 per cent of dry matter contained 5.798 per cent of ash. The percentage of chlorin was 1.591, equivalent to 2.624 per cent of sodium chlorid. The percentage of calcium oxid was 0.787 per cent, and of phosphoric acid 1.38 per cent, the ratio between the two being 1:1.75.

Cheese made from separator skim milk contained 55.243 per cent of dry matter, 7.473 per cent of ash, 2.154 per cent of chlorin (equivalent to 3.553 per cent of sodium chlorid), 1.102 per cent of calcium chlorid, and 1.845 per cent of phosphoric acid, the ratio between the last two being 1:1.67.

The composition of milk and the conditions affecting it, as shown by Bell's analyses, J. F. LIVERSEEGE (*Analyst, 20 (1895), Jan., pp. 7–12*).—The author discusses the analyses of the milk of 273 cows and 55 herds with reference to the milk standard of the English Society of Public Analysts, and with reference to the effect of breed, time of milking, and food on the composition of the milk.

"These analyses show that—

"(1) With 4 very slight exceptions, all the mixed milks are up to the society's standard [8.5 per cent solids-not-fat and 3 per cent fat].

"(2) Only 4 per cent of the milk from the single cows would show signs of much adulteration, as judged by the society's standard, if allowance is made for excess of the other constituents.

"(3) Analyses by the Bell method may give from 0.40 less to 0.26 per cent more than the calculated figures.

"(4) The longer the time between milking the lower will be the fat in milk.

"(5) With the exception of breed, the other conditions have much less effect on the proportion of poor milks."

Note on Recknagel's phenomenon, H. D. RICHMOND (*Analyst, 20 (1895), Jan., pp. 1–3*).—Recknagel, and later Vieth and other chemists, observed that the specific gravity of milk immediately after milking was lower than after standing some time. This Recknagel attributed to a swelling of the casein. The author reviews the subject and refers to some preliminary experiments without giving any details.

"It seems probable that Recknagel's explanation that a change in the casein occurs is correct, and that this is due to an enzyme (possibly the enzyme which causes the changes within the udder); it would appear from this that milk is still a living tissue after secretion. It is probable, then, that fore-milk (*i. e.*, milk that has remained ready formed for some time within the udder) will show much less rise than the later portions (which are drawn away as secreted). Preliminary experiments have shown indications of this being the case."

Investigations of the fat content of milk from individual cows, L. Hansen (*Ugeskr. Landm., 40 (1895), pp. 25–27*).—The author determined the yield of milk, and the percentage of cream in the milk as shown by Fjord's control centrifuge, in case of 6 different herds for a period of 3 years, with the following average results per year:

Average annual record for 6 herds of cows.

Herd number.	Number of cows.	Average annual milk yield per cow.	Average cream content.	Corresponding to fat.
		Pounds.	*Per cent.*	*Per cent.*
1	18	5,867	5.1	3.6
2	16	5,500	5.0	3.5
3	13	5,500	5.1	3.6
4	14	5,867	4.6	3.2
5	11	4,767	4.6	3.2
6	4	5,133	4.4	3.1

Herd No. 1, giving the largest average yield of milk, produced the richest milk, or at least as rich milk as herd No. 3, which yielded 1,100 lbs. less milk per head during the 3 years considered. All herds were well fed and cared for, and most likely of the same breed, viz, the ordinary Danish red breed of milch cows. A detailed statement of the average cost of production of 1 lb. of butter in case of 36 cows is given, the amount of milk, butter, and skim milk and their value, as well as the cost of the feed eaten being noted in each case; the period considered is 1 year. The yields of milk ranged from 3,788 to 10,068 lbs.; of butter, from 121.9 to 394.8 lbs.; and the cost of producing 1 lb. of butter from 12.9 to 30.5 cents.—F. W. WOLL.

Churning experiments, J. L. Hills (*Vermont Sta. Rpt. 1893, pp. 100–106*).

Sweet and ripened cream (pp. 101, 102).—The results are summarized for 33 churnings of sweet cream and 81 of sour cream as follows:

Results of churning sweet and ripened cream.

Condition of churning.	Number of churnings.	Milk taken as cream.[1]	Fat in buttermilk.	Fat in butter.	Curd in butter.	Temperature of churning.	Time of churning.
		Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Deg. F.*	*Minutes.*
Sweet	33	16.8	0.36	81.93	0.66	57	34
Ripened	81	15.1	.24	82.05	.73	57	27

[1] This heading refers to the proportion of the weight of the cream to the weight of the milk from which it was obtained.

The sweet cream butters included 5 made by the butter extractor with an average of 80.03 per cent of fat. The sweet cream butter contained no more curd in these experiments than the ripened cream butter.

"At the same average temperature of churning, the sweet cream took a quarter as long again to churn and lost half as much again of fat in the buttermilk. This may be due in part to the fact that the sweet cream was less concentrated than the ripened cream."

Deep setting and separator cream (p. 102).—A series of 18 churnings with Cooley cream and separator cream, all made by the same butter maker, gave the following average results:

Churning Cooley and separator cream.

Separator.	Number of churnings.	Milk taken as cream.[1]	Fat in buttermilk.	Fat in butter.	Curd in butter.	Temperature of churning.	Time of churning.
		Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Deg. F.*	*Minutes.*
Cooley cream	10	19.9	0.43	80.70	0.66	60	39
Separator cream	8	16.7	.46	82.16	.57	59	35

[1] This heading refers to the proportion of the weight of the cream to the weight of the milk from which it was obtained.

Some of these churnings were made during the summer, which accounts for the high percentage of fat in the buttermilk.

"Both creams were thin, the deep setting cream containing practically one fifth of the milk. There was little difference in time or temperature of churning. The butter made from the deep setting process, however, contained the least fat and the most curd."

Varying concentration of cream (pp. 102, 103).—The results of 110 churnings of cream of different thickness are summarized in the following table:

Churning thick and thin cream.

	Relation of cream to milk from which obtained, by weight.	Number of churnings.	Acidity.[1]	Fat in buttermilk.	Fat in butter.	Curd in butter.	Temperature of churning.	Time of churning.
	Per cent.			*Per cent.*	*Per cent.*	*Per cent.*	*Deg. F.*	*Minutes.*
Very thick	10 to 11.9	6	31.0	0.21	81.73	....	56	14
Thick	12 to 13.9	20	31.0	.23	82.78	....	55	24
Medium	14 to 15.9	35	33.0	.17	82.47	0.67	56	28
Thin	16 to 17.9	27	34.5	.33	82.30	.59	56	30
Very thin	18 to 21	20	35.0	.35	81.03	.66	58	34
Exceedingly thin	32.1	2	49.0	.35	81.82	....	56	68
Thick and medium, average	10 to 15.9	61	32.0	.19	82.50	....	56	25
Thin, average	16 to 32.1	49	35.0	.34	81.88	....	57	33

[1] Expressed in cubic centimeters of tenth normal alkali needed to neutralize 50 cc. of cream.

"Under conditions where there is body enough of cream to ripen well, regardless of concentration, it is probably safe to say that the thicker the cream the better, inasmuch as skimming is as satisfactory, the completeness and time of churning, and quality of the butter is better, a larger proportion of skim milk is delivered to the patron, and vat and churn room and handling are saved."

Varying temperatures of churning (pp. 103, 104).—The results are tabulated for 101 churnings at temperatures varying from 49 to 68° F. At temperatures below 56° F. the average percentage of fat in the buttermilk was 0.17, and the average time of churning 32 minutes; and at temperatures above 56° the average percentage of fat in the buttermilk was 0.33, and the average time of churning 23 minutes.

"A study of the table shows a connection between churning temperature and the results of churning. As the temperature rises, the loss of fat in the buttermilk increases, the cream becomes thinner, the percentage of fat in the butter decreases, and the time of churning shortens. There is no apparent effect upon the percentage of curd in the butter. These points indicate that the proper answer to the often-asked question regarding the temperature of churning is: Churn at the lowest temperature which under the individual conditions will produce exhaustive churning and make a good quality of butter in a reasonable time."

Varying acidities of cream (pp. 104, 105.)—The acidity was determined by Mann's acid test. The results are summarized of 51 trials in which the acidity varied from 27 to 42 cc. decinormal alkali per 50 cc. of cream.

"The only effect of increasing acidity of the cream shown in the table is in the composition of the butter. This again may be due to a thinner cream."

Varying lengths of time in churning (pp. 105, 106).—The results of 91 trials are summarized in which the time of churning varied from 15 minutes or less to 1 hour or more.

"There seems to be no connection between acidity of the cream, the temperature of churning, the curd in the butter, and the time occupied in the operation. The longer churnings, however, were on the thinner creams and lower temperatures, which is in line with the results shown in the table. The effect of lower temperature appears to be to increase the percentage of fat in the butter; of thinner cream, to decrease it, and we find in this case but slight difference between the character of the butter made in less or more than 25 minutes. It is difficult to say which of the factors had the most influence in the slight difference."

Summary (p. 106).—

"(1) In these experiments the per cent of fat in the butter appears lessened by thinning the cream, by an increase in churning temperatures, by an increase in the acidity of the cream, by the lengthening of the time of churning, and by the change from a separator to a deep setting system. There was no marked difference in the fat percentages of sweet and sour cream butters.

"(2) The per cent of curd in butters did not appear to be affected by the length of time or the varying temperatures of churning. The sweet cream butters contained more curd than those made from sour cream, and the deep setting butters more than did the separator-made goods.

"(3) The churnings were most exhaustive with thick and ripened creams at low temperatures, while varying acidities, length of churning, and methods of cream separation showed little effect.

"(4) The conditions most favorable in these experiments to exhaustive churning of a firm (high percentage of fat) butter from separator cream, appeared to be, (1) a thick cream containing 10 to 16 per cent of the original milk; (2) ripened cream, unless churning at 54° or below; (3) a low churning temperature."

Swedish butter exhibitions during 1894, N. ENGSTRÖM (*Tidskr. Landtmän, 15* (*1894*), *pp. 922–926*).—The 248 creameries participating in the Swedish butter exhibitions conducted at Malmö and Gothenburg during 1894 exhibited 880 tubs of butter in all. The average water content of all samples of butter was 13.87 per cent, the range being from 9.13 to 20.22 per cent; 659 samples, or 74.9 per cent, contained between 12 and 15 per cent of water; and only 36 samples, or 4.1 per cent, contained more than 16 per cent of water.—F. W. WOLL.

Manufacture of sweet curd cheese, T. L. HÆCKER (*Minnesota Sta. Bul. 35, pp. 104–128, figs. 7*).—Detailed directions are given for making Edam and Gouda cheese. Gouda cheese is believed to be the kind best adapted for the home dairy, since "(1) the milk is worked warm, fresh from the cow; (2) it requires less than 2 hours to do the work; (3) the cheese can be cured in a cellar or in any damp, cool place; (4) it is a good keeper; (5) it is nutritious and palatable." The data are given for 25 trials in making Edam cheese, 9 in making Gouda cheese, and 10 in making Emmenthaler or Swiss cheese. These data include the principal conditions of manufacture, and the composition of the milk, whey, and cheese, and in the case of Gouda and Swiss cheese the losses of solids and fat during manufacture.

In the manufacture of Edam cheese there was a loss in the whey of from 5.66 to 7.98 lbs. of solids per 100 lbs. of milk, and from 0.3 to 0.87 lb. of fat. In making Gouda cheese from 42.87 to 47.07 per cent of the solids in the milk and from 7.1 to 12.38 per cent of the fat in the milk were lost in the whey. In making Swiss cheese the loss of solids in the whey ranged from 46.97 to 59.93 per cent and the loss of fat from 16.44 to 20.5 per cent. The whey in making all 3 kinds of cheese frequently contained more than 0.5 per cent of fat. The fat content was especially large in that of the Swiss cheese, where it ranged from 0.74 to 1.01 per cent. In a number of cases whey from making Emmenthaler cheese was run through the separator and the cream ripened and churned. The butter thus obtained scored 91 or 92 points.

> "Whey butter as usually made is a very low grade of goods, selling about on a par with the grade generally termed 'packing stock, poor,' which sells for 10 cts. when extra dairy butter sells at 20 cts. By running the whey through a separator and ripening the cream with good lactic ferment the quality of the butter can be improved 25 to 50 per cent."

Method of preventing mites in cheese, P. B. SEGELCKE (*Fifth Rpt. Danish State Agl. Councilors, 1893, pp. 125, 126*).—The author gives the following method for preventing mites in cheese: The ceiling, walls, floor, and shelving of the curing room are whitewashed several times until the mites are destroyed. The cheese is first placed in a brine bath for 24 hours, and then in the curing room for 14 days, during which time it is wiped off daily. After 14 days it is thoroughly scraped and washed in lime water, placed on shelves, and kept clean; if a layer of slimy mold should again appear, the cheese must again be scraped and washed with lime.—F. W. WOLL.

Miscellaneous notes on handling milk, J. L. HILLS (*Vermont Sta. Rpt. 1893, p. 111*).—To compare the losses in making butter from milk containing large and small fat globules, the milk of 2 groups of cows possessing these characteristics was creamed in cold deep setting, the cream ripened, and churned at 58° F. The percentages of fat in the skim milk, buttermilk, and butter and the mechanical losses are tabulated. "There was but one third the loss in the creaming of the milk containing the larger globules, and in this case there was also less mechanical loss."

The results of creaming milk of cows in different stages of lactation in cold deep setting and by separator are given.

Tests of cream separators, H. P. ARMSBY, W. H. CALDWELL, and L. E. REBER (*Pennsylvania Sta. Bul. 27, pp. 23*).—Tests are reported of the De Laval Alpha Acme, De Laval Alpha Turbine, United States No. 3, and Standard Russian separators. In these tests the number of runs with each machine varied from 4 to 10. The completeness of the separation was determined by weighing and analyzing the milk used and the products obtained so as to keep a close check upon the results. The results of the tests are fully tabulated, together with results of tests made at Vermont and New York Cornell stations, and the results of estimation of the steam consumption of belt and turbine separators are given. The average completeness of separation was as follows:

	Per cent.
De Laval Alpha Acme	98.31
De Laval Alpha Turbine	99.23
United States No. 3	98.08
Standard Russian	97.10

"Under the conditions of our tests, the steam was used very wastefully. Our conditions, however, were not widely different from those of very many small creameries, where a comparatively small and cheap engine is employed for the purposes of the creamery solely. Under such conditions it would appear that simple determinations of the horsepower required to drive a separator are of no practical value to the creamery man, since they furnish no measure of the amount of fuel which he will actually have to burn to operate the machines. . . .

"The comparison of the steam consumption shows that under our conditions the turbine separators were more economical of steam than the belt separators. That is to say, while the turbine uses steam extravagantly, the small engine of the average creamery uses it still more extravagantly, and the introduction of a turbine is likely to result in a saving of fuel. . . .

"The conclusion would seem to be that in small plants where a separate engine must be used for the creamery work a turbine will give the best economy, but that there is a point in the size of the plant were the economy of the belt machine will come to exceed that of the turbine."

Tests of dairy apparatus, J. L. HILLS (*Vermont Sta. Rpt. 1893, pp. 92–100*).—The results are given of tests of a number of different kinds of separators, made in connection with the Vermont Dairy School, and the determination of the power required for running by means of a dynamometer. In most of these trials the cream was ripened and churned to butter. A record is given for the whole process of butter making. The average results with each kind of separator are shown in the following table:

Tests of separators.

Separator.	Number of runs.	Speed in revolutions per minute.	Amount of milk separated per hour.	Horsepower used to separate 1,000 lbs. of milk per hour.	Fat content of— Whole milk.	Fat content of— Skim milk.	Fat content of— Bowl slop.	Proportion of fat in whole milk recovered in butter. Theoretical.	Proportion of fat in whole milk recovered in butter. Actual.
			Lbs.		*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
De Laval Alpha Turbine	4	5,780	1,800	....	4.35	0.06	0.24	98.0	89.3

TECHNOLOGY.

The heating power of Wyoming coal and oil, with a description of the bomb calorimeter, E. E. SLOSSON and L. C. COLBURN (*University of Wyoming Spec. Bul., Jan., 1895, pp. 32, fig. 1*).—Analyses and tests of the fuel value of 54 samples of Wyoming coal, and tests of fuel value of 2 samples of Texas coal, 1 of fat pine knots, 6 of petroleum, and 2 of asphalt are reported and discussed in some detail. The average results of the tests of Wyoming coals were as follows: Calories per gram 6,282, foot-pounds per pound of coal 8,779,000, pounds of water at 212° F. evaporated by 1 lb. of coal 11.7. In case of the petroleum the calories varied from 10,430 to 10,927, the foot-pounds from 14,571,000 to 15,204,000, and the pounds of water evaporated from 19.4 to 22.24. Mahler's calorimetric apparatus is illustrated and described and the principles and methods of calorimetry are explained.

Analyses of maple sugar, sirups, etc., J. L. HILLS and B. O. WHITE (*Vermont Sta. Rpt. 1893, p. 29*).—The percentages of sugar in 21 samples are reported.

Effect of deep and shallow tapping of maple trees (*Garden and Forest, 8 (1895), p. 150*).—Deep tapping gives a much greater flow than when tapped but an inch deep.

Report on experiments in wine making in 1893, E. KAYSER (*Bul. Min. Agr. France, 13 (1894), No 8, pp. 874–884*).

A contribution to the study of the utilization of the refuse of wine making, E. SILVA (*Staz. Sper. Agr. Ital., 28 (1895), No. 1, pp. 5–18*).

AGRICULTURAL ENGINEERING.

Farm drainage, C. L. NEWMAN (*Arkansas Sta. Bul. 32, pp. 33–54, fig. 1*).—A popular discussion of this subject under the following heads: Protection from surface washing (plant cover, hillside ditches, and terraces), and drainage of wet lands (indications of the need of drainage, open ditches, and underdrains or covered ditches), with an appendix describing a homemade terracing instrument.

The artesian wells of southern Wyoming, J. D. CONLEY (*Wyoming Sta. Rpt. 1894, pp. 87–122*).—A reprint of Bulletin 20 of the station (E. S. R., 6, p. 848).

The Harvey water motor, A. A. JOHNSON (*Wyoming Sta. Rpt. 1894, pp. 66–72, figs. 6*).—A reprint from Bulletin 18 of the station (E. S. R., 6, p. 346).

An electric plow, F. BRUTSCHKE (*Fühling's landw. Ztg., 44 (1895), No. 5, pp. 158–165, fig. 1*).

Plows, rollers, fertilizer distributors, and potato planters, RINGELMANN (*Jour. Agr. Prat., 59 (1895), No. 11, pp. 388–393, figs. 8*).—Descriptions of agricultural implements tested.

Heel scrape and scooter, R. L. BENNETT and G. B. IRBY (*Arkansas Sta. Bul. 31, pp. 28–31, fig. 1*).—This implement is described and the character of its work commended.

Agricultural implements, A. DEBAINS (*Les machines agricoles sur le terrain. Paris*).—Separate volumes treat of cultivators, seeders, and harvesting machines.

Proceedings of the Virginia Good Roads Convention held in Richmond, Virginia, October 18, 1894 (*U. S. Dept. Agr., Office of Road Inquiry Bul. 11, pp. 62, fig. 1*).—An account of the proceedings, giving text of remarks, addresses, and papers. Addresses were made by G. L. Christian, president of the Richmond Chamber of Commerce, and S. W. Corbin, president of the State Board of Agriculture, and the following papers were read: "What our bad roads cost us," by C. Coleman; "How to produce the means to build good roads," by J. F. Jackson; "Our highways, their construction and maintenance," by C. E. Ashburner; "The use of convict labor on public roads," by J. Graham, jr.; "Country road bridges," by C. C. Wentworth; "Stone and shell roads," by D. C. Humphreys.

STATISTICS.

Report of the statistician (*U. S. Dept. Agr., Division of Statistics Rpt. 123, n. ser., pp. 58*).—The statistics given in this report relate to the number and value of farm animals in the different States, the cotton crop of 1894, live stock in Great Britain and Ireland, and the cotton crop of India for 1894. The report also contains notice of a French Congress on popular credit, notes on the wheat crop of Victoria (Australia), notes on foreign agriculture, and transportation rates.

Report of the statistician (*U. S. Dept. Agr., Division of Statistics Rpt. 124, n. ser., pp. 59–106*).—This report treats of the distribution and consumption of corn, the consumption of wheat per capita in the United States, the wheat crop of the world, prices of wheat since 1865, wholesale prices of principal agricultural products, report of European agents, and transportation rates.

Reports of director and of treasurer of Vermont Station (*Vermont Sta. Rpt. 1893, pp. 9–16*).—This includes the review of the work of the year by the director, list of bulletins published, and matter of general interest, together with the treasurer's report for the fiscal year ending June 30, 1893. In connection with a revision of the station mailing list by return postal cards which took place during the year, it is stated that "over 95 per cent of the cards were returned, and a large number of names of persons who had died or removed to unknown addresses were stricken from the list."

Report of Wyoming Station for 1894 (*Wyoming Sta. Rpt. 1894, pp. 138*).—This includes a report by the director on the work of the year; treasurer's report for the fiscal year ending June 30, 1894; and brief reports by the agriculturist and horticulturist, physicist, meteorologist, botanist, chemist, and geologist; together with reprints of the bulletins published during the year.

Remarks on the work of the Posen Experiment Station in 1894, M. GERLACH (*Landw. Centbl. Posen, 23 (1895), No. 8, pp. 44, 45*).

NOTES.

Massachusetts Stations.—The two stations in Massachusetts have been united under the name of the Hatch Experiment Station of the Massachusetts Agricultural College. President H. H. Goodell has been elected director pro tem. The reorganization will be completed at the June meeting of the board of control.

Association of American Agricultural Colleges and Experiment Stations.—Notice has been issued that the next annual meeting of the Association will be held at Denver, Colorado, beginning July 16, 1895.

Soil tests in Virginia.—At a meeting of the Virginia State Board of Agriculture, April 10, 1895, called for the purpose of arranging for soil tests in the State, a resolution was reported and approved authorizing the Commissioner of Agriculture, in conjunction with the Committee of Agricultural and Analytical Chemistry of the Board, to expend $500 for conducting fertilizer tests in four different sections of the State, comprising the tobacco, corn, grass, and truck lands, and $1,000 for a preliminary examination of the composition, texture, and relations to moisture and crops of the principal soils of the State, under the advice of the Chief of the Division of Agricultural Soils of this Department.

Four points were selected for experiment, as follows: For bright tobacco, Pittsylvania County, near Danville; for corn, Hanover or Goochland County; for trucks, the peninsula near Williamsburg; for grasses, Augusta County.

Personal Mention.—Dr. J. P. Lotsy, associate in botany at Johns Hopkins University, has accepted the directorship of the botanical gardens of Java.

Dr. A. Morgen, for several years first assistant at the Halle Station, has been appointed professor of agricultural chemistry and director of the experiment station at Hohenheim, Germany, to succeed Prof. Emil von Wolff, who has retired.

Dr. Th. Pfeiffer, chemist to the German Agricultural Society, and formerly connected with the Göttingen Station, under Henneberg, has been elected professor of agricultural chemistry in the University of Jena. He will be succeeded by Dr. J. H. Vogel.

EXPERIMENT STATION RECORD.

Vol. VI. No. 11.

Twenty-six years ago, through the activity of Dr. F. Nobbe, the experiment station for plant physiology connected with the Forestry Academy at Tharand, Germany, offered to assist the farmers in the selection and purchase of seed. The station received an annual grant of about $450 from the Agricultural Society of Dresden to aid in carrying on its work. This was the beginning of the seed control, which from that time until the present has steadily grown in extent and in usefulness, especially in European countries. Its history, present extent, methods of work, etc., are described in detail in an interesting paper by B. Jonsson[1] on the seed control stations of the world, which includes a very complete bibliography of the subject. According to this paper there are now 117 stations in active operation outside of the United States. The different countries are said to be represented as follows: Belgium 9 stations, Bulgaria 3, Denmark 1, England and Scotland 2, France 1, Holland 4, Italy 1, Norway 3, Portugal 3, Roumania 1, Russia 7, Spain 1, Switzerland 2, Germany 38, Hungary 6, Austria 14, Sweden 16, Brazil 1, Japan 1, and Java 3.

In 1877 29 seed control stations were established in Germany, 7 of which were devoted to seed control exclusively, while the rest were combined chemical and seed control stations. The first seed control station in Austria was established in 1870, in Denmark in 1871, in Belgium in 1875, and in Switzerland and Russia in 1876.

The organization and working plans of the different stations vary to suit the individual needs of the work, but the modified plans as suggested by Dr. Nobbe are the basis for all. The methods of the German stations have been fully described in this journal by Dr. Oscar Burchard (E. S. R., 4, pp. 793, 882). In all cases a certain definite sample is required, the size of which depends on the seed to be examined. For the smaller and lighter seeds 100 gm. is required, while for the larger seeds the weight of the average sample must be at least 250 gm. From these samples smaller ones are taken and tested for their purity, germinative ability, and intrinsic worth. The weight of these smaller samples varies from 2 gm. for the smaller and lighter seeds to 50 gm.

---

[1] Kgl. Landt. Akad. Handl. Tidskr., 33, pp. 257-286 and 321-372.

for such large seeds as corn, beans, beet seed, etc. The time for germination has been experimentally determined for the different kinds of seed and the germination in a certain definite time of every lot tested is compared with the standard for that kind. The standards for purity, germinative ability, and intrinsic worth vary in different countries, each having its own.

The methods by which the control is secured differ in different countries. In some countries this is brought about through legislative action requiring all seed offered for sale to be up to a certain definite quality. In others the same end is secured by a mutual agreement between the wholesale dealers and the stations, whereby dealers place themselves voluntarily under the control of the station and the station certifies to the quality of the seed placed on the market. In other cases there is a combination of these two methods of control, governmental supervision being provided for local dealers and either private or control contract for those outside the State's jurisdiction. Under the private contract the station has no connection with the consumer, but it simply reports to the wholesale dealer on the qualitity of the seed. Under what is known as the control contract the station certifies to the quality of seed and a copy of this certificate is furnished to every purchaser. Under certain conditions the consumer is allowed a free reëxamination of any seed purchased under the control contract, and if a departure of more than 5 per cent from the guaranty is found the dealer is required to reimburse him.

The first attempt in the United States in seed testing was made at the Connecticut State Station in 1877, and two years later the North Carolina Station equipped itself for such work. At the present time several of the experiment stations are prepared to test samples of seed sent them, but they exert no control over their sale. Systematic effort was commenced by this Department about a year ago to collect information on the commercial side of the seed industry in this country and to study the quality of the seed placed upon the market.

The benefits resulting from the seed control in Europe are apparent in the improvement of the quality of seed in general and in the security which it gives to the buyer. The reports of these stations show that the quality of seed has steadily improved since the introduction of seed control. This is especially true in regard to trueness to name and freedom from weed seeds.

The necessity for seed control in this country is not less than in Europe. It is second only in importance to the control of the sale of commercial fertilizers now exercised so generally in the States where fertilizers are used.

The following is a list of the seed control stations now in active operation in different countries, with the date of their establishment, taken from the article by Jonsson referred to above.

Belgium: Antwerp, Courtrai, Ghent (1875), Gembloux (1875), Hasselt (1878), Liege (1878), Louvain, Mons, Roulers.

Bulgaria: Rustchuk (1892), Sadova (1892), Plevna (1892).

Denmark: Copenhagen (1871).

England and Scotland: London, Edinburgh.

France: Paris (1884).

Holland: Goes (1889), Groningen (1889), Hoorn (1889), Wageningen (1877).

Italy: Modena (1890).

Norway: Hamar, Christiania, Frondhjem.

Portugal: Evora (1886), Lisbon (1886), Oporto (1886).

Roumania: Bucharest (1887).

Russia (including Finland): Helsingfors (1881), Riga (1876), St. Petersburg (1880), Sobieszyn (1892), Tver (1892), Warsaw (1880), Aabo (1881).

Spain: Madrid (1891).

Switzerland: Rüti (1876), Zurich (1876).

Germany: (1) *Prussia:* Arendsee (1879), Bonn (1881), Bremervorde (1876), Breslau (1875), Dahme (1876), Dantzic (1876), Ebstorf (1871), Eldena (1878), Göttingen (1876), Halle (1877), Hildesheim (1878), Insterburg (1877), Kempen (1883), Kiel (1874), Königsberg (1875), Köslin (1893), Marburg (1876), Münster (1871), Posen (1873), Wiesbaden (1881). (2) *Bavaria:* Augsburg, Baireuth (1876), Landshut (1876), Munich (1872), Speyer, Triesdorf (1876), Würzburg (1881). (3) *Saxony:* Tharand (1869). (4) *Baden:* Karlsruhe (1872). (5) *Hesse-Darmstadt:* Darmstadt (1871). (6) *Oldenburg:* Oldenburg (1876). (7) *Brunswick:* Brunswick (1877). (8) *Mecklenburg-Schwerin:* Rostock (1875). (9) *Saxe-Weimar:* Jena. (10) *Alsace-Lorraine:* Rufach (1874). (11) *Bremen:* Bremen (1877). (12) *Hamburg:* Hamburg (State) (1891), Hamburg (private) 1891.

Hungary: Budapest (1882), Debreczin, Keszthely, Kassa, Kolosmonostor, Altenberg (1878).

Austria: Czernislov, Dublany, Feldkirch (1876), Grätz (1872), Kaaden (1877) Neutitschein (1891), Oberhermsdorf, Prague (1877), Prerau (1884), St. Michele (1874), Tabor (1874), Troppau (1892), Vienna (State) (1870), Vienna (agricultural society) (1881).

Sweden: Borås, Falun, Gefle, Halmstad, Hernosand, Jönköping, Kalmar, Christianstad, Linköping, Luleå, Oerebro, Skara, Stockholm, Svalof, Upsala, Westerås.

Brazil: São Paulo (1887).

Japan: Tokyo (1893), with substations.

Java: Kagok-Tegal, Pasoeroean, Buitenzorg.

THE PHYSICAL PROPERTIES OF THE SOIL.[1]

Dr. Ewald Wollny.

PART 3.

IV. THE BEHAVIOR OF THE SOIL TOWARD AIR AND GASES.

THE AIR CAPACITY (OR POROSITY) OF THE SOIL.

This is expressed by the ratio of the volume of the air spaces to the total volume of the soil. The volume of the pores or intergranular spaces varies in natural soils, as we have already seen (p. 764) within wide limits—in the dry state from 20 to 85.3 per cent. In one and the same soil the air capacity depends principally on structural conditions. In the dry state the volume of the air spaces is greater the smaller the particles. Stirring and flocculation increase the volume of the pores generally to a considerable extent, while the pressing together of the soil produces the opposite result. It may be mentioned further that the quantity of air inclosed in a soil decreases as the proportion of stones increases.

With the increase in the quantity of water present the volume of the pores of course decreases, but to a varying extent according to the water capacity. In the moist state clay and humus contain the smallest quantity of air of any of the soil constituents; in fact the air may be entirely absent when these substances are saturated with water. The quantity of air in the wet mass always increases with the quantity of coarse-grained constituents. The influence of water on the volume of the pores is less marked in crumbly than in powdery soils, because in the former the noncapillary spaces are not filled with water. The decrease in the quantity of air due to an increase in the density of the mass is greater in the moist than in the dry condition.

From what has been said regarding the influence of the quantity of water in a soil on the volume of the pores it is plain that the quantity of air in the soil increases during drought and decreases correspondingly with an increased precipitation. The extent of the influence of the soil in this particular is determined by its mechanical structure.[2]

The air inclosed in the soil is seldom stagnant, but is generally in constant motion, causing an exchange of air between the atmosphere and the soil. This motion is due to the variations in atmospheric pressure, temperature, and wind movement.

---

[1] Continued from p. 863.

[2] E. Wollny, Forsch. Geb. agr. Phys., 8, p. 371.

THE PERMEABILITY OF THE SOIL FOR AIR.

This property is measured by the quantities of air which pass through the soil, other conditions being the same. Except under special conditions it does not depend upon the volume of the pores, but is influenced primarily by the size of the pores, since the latter determines almost exclusively the resistance offered to the circulation of the air. The permeability necessarily increases as this resistance diminishes, and is therefore smaller the smaller the soil particles, and *vice versa*.

Of the different soil constituents in the dry state, clay is the least permeable to air; and permeability increases generally with the quantity of quartz present. Soils consisting of humus alone behave, when dry, similarly to the coarse-grained sands. In soils made up of constituents varying considerably from one another in the size of the particles, the permeability of the whole mass depends principally on the finest-grained material. The remarkable permeability of most sands can, therefore, be reduced considerably by the admixture of comparatively small quantities of some fine-grained material, such as clay, loam, or marl.

In the case of stratified soils the permeability depends entirely on the finest grained layer, even if the layer is very thin. In a very impermeable soil the permeability is increased to a remarkable extent by the formation of the crumbly structure. With an increase of humidity the permeability of a soil for air diminishes, and more strongly the greater the water capacity of the soil. All soils rich in clay and humus become impermeable at a point below saturation. Crumbly soils have their permeability affected to a very much less degree by an increase in humidity than soils having a separate grain structure. If a soil is wet only in the upper layers the entrance and exit of air is hindered in proportion to the fineness of the grains. In soils rich in clay and humus this may result in absolute impermeability, even with slight precipitation.

If air is forced by pressure through soil, the quantity of air passing is proportional to the pressure, and inversely proportional to the thickness of the layer, so long as the velocity does not exceed 0.05 meter. As soon as this limit is exceeded the volume of air does not diminish as the pressure diminishes or as the thickness of the layer increases, but to a less extent, and *vice versa*.[1]

THE DIFFUSION OF GASES FROM THE SOIL.

The pores of the soil contain, along with atmospheric air and water vapor, different gases, of which carbonic acid is the most important, as it is present in the largest quantities. The carbonic acid is due principally to the decomposition of organic substances. The amount present depends upon the richness of the soil in humus and the rapidity of decomposition, but it is almost always much more abundant in the soil than in the atmosphere. Under these circumstances it is of interest to note that there is a constant movement in the soil atmosphere not due to external influences, but to diffusion, *i. e.*, the tendency for the external and internal gases to come into equilibrium.

---

[1] H. Fleck, Ztschr. Biol., 16, p. 42. Erster Jahresbericht der chemischen Centralstelle für öffentliche Gesundheitspflege in Dresden. F. Renk, Ztschr. Biol., 15. G. Ammon, Forsch. Geb. agr. Phys., 3, p. 209. D. von Welitschkowsky, Arch. Hyg., 11. R. Heinrich, Grundlagen der Beurtheilung der Ackerkrume, 1882, pp. 123, 221. E. Wollny, Forsch. Geb. agr. Phys., 16, p. 193.

The diffusion of the carbonic acid (as well as ammonia and other gases) from the soil at a constant temperature depends principally on the sum of the pores of the cross section and not on their size. Hence the absolute quantity of diffused gases is larger the greater the total volume of the pores, and *vice versa.* Every decrease in the volume of the pores, whether due to pressure or to an increase of moisture in the soil, is accompanied by a decrease in the quantity of gas diffused. The escape of carbonic acid into the atmosphere by diffusion decreases with the fineness of the grains of the soil, the compactness of their arrangement, and the greater the water capacity of the soil, and *vice versa.* The quantity of carbonic acid diffused diminishes as the thickness of the soil increases, but to a less extent. In soils which become superficially saturated, and into which water penetrates slowly, the diffusion of carbonic acid is considerably diminished or brought to a standstill.[1]

THE ABSORPTIVE CAPACITY (OR CONDENSATION CAPACITY) OF THE SOIL FOR GASES.

Absorption, in the widest sense of the word, is a molecular phenomenon and includes all those causes which bring about the retention of gas molecules on and in solid bodies. It is only a matter of custom to distinguish between hygroscopicity and gas absorption (absorption in the narrow sense), which are essentially identical phenomena. The retention of the gas molecules is caused by a series of separate processes. These are discussed below.

Surface attraction.—There are on the surface of all solid bodies molecular forces related to adhesion, which attract the nearest gas molecules to the surface of the solid body, and there force them together in a dense, partly liquid or perhaps solid envelope, until an equilibrium is reached which remains undisturbed until the constitution of the surrounding medium changes. This process takes place almost instantaneously and with great energy, so that in the beginning, at least, the whole process of absorption may be attributed to it. It also causes initially a rapid rise of the absorption curve and produces a considerable amount of heat, which gives the impetus to a series of further phenomena.

Molecular penetration.—The attracted gas particles penetrate to a certain extent into the intramolecular spaces of the solid body in much the same way as gases are absorbed by liquids, partly on account of the high pressure to which they are subjected and partly on account of the very fine capillaries. This process takes place more slowly than surface attraction, and ceases when the resistance opposed to the penetration of the gas molecules can no longer be overcome.

---

[1] F. Hannen, Forsch. Geb. agr. Phys., 15, p. 1.

Absorption.—Owing to surface attraction, an exceedingly thin layer of liquid is very soon formed over the surface of the solid body, and this layer now absorbs gases. Assisted by the high pressure to which this layer is subjected (Bunsen estimates the pressure at hundreds of atmospheres) its capacity for absorption of gases rises to a degree far exceeding our ideas of such processes. This process may also continue for years before reaching its conclusion (Bunsen).

Chemical reactions.—Leaving out of account simple chemical attractions, which do not belong in the realm of gas absorption, there are widely varying, and under ordinary circumstances for the most part unknown, chemical activities between the molecules of the solid body and those of the penetrating gas. The high capillary pressure together with the disengagement of considerable quantities of heat during the initial condensation bring about and keep in action processes which chemical affinity alone would not cause.

The numerous investigations on this subject have given the following results: All the soil constituents have a not inconsiderable absorptive capacity, which is greatest in the case of humus (and ferric oxid), next highest in clay, and least in quartz. Mixed soils behave as their individual constituents. The absorptive capacity increases in any case with the fineness of the particles, and decreases with a rise of temperature. In the absorption of water vapor from air saturated with moisture the latter law is modified only to the extent that the absolute quantity of water increases with the temperature; in which case the influence of the rise in temperature is almost eliminated by the increase in humidity. If the absolute humidity of the air is constant while the temperature rises the influence is the same as that observed in the case of gas absorption. At a constant temperature the hygroscopicity increases with the relative humidity of the air. If the soil is more than hygroscopically moist the gas absorption we have so far considered is replaced by the absorption of gases in the soil water. Rising temperatures accelerate the condensation process. Gases are in general more easily absorbed the more readily they alter their molecular arrangement and the more easily they decompose.[1]

The significance of the absorptive capacity in relation to the fertility of the soil is often overestimated. Gases capable of increasing the supply of fertilizing material occur only in very minute quantity in the atmosphere or in the soil air. The absorption of oxygen is of most importance, because it is through this means that the soil is capable of supplying the oxygen necessary for the respiration of the plant roots when the supply from the atmosphere is cut off by excessive moisture. The hygroscopic water, which occurs to a considerable extent in many soils, is also of comparatively slight importance for vegetation, because the plants wilt before the quantity of water has fallen sufficiently to make it possible for an absorption of water vapor to take place at all.

---

[1] G. Ammon, Forsch. Geb. agr. Phys., 2, p. 1. A. von Dobeneck, Ibid., p. 163. Both these articles contain a complete general review of the copious literature on this subject.

THE COMPOSITION OF THE SOIL ATMOSPHERE.

The air inclosed in the soil differs from atmospheric air principally in containing more carbonic acid, less oxygen, and more moisture. From the well-established fact that the soil atmosphere becomes richer in carbonic acid in proportion to the diminution of its oxygen, in such a way that the volume of carbonic acid and oxygen together remains constant, we must infer that the carbonic acid is the product of processes of oxidation. Of the latter the most important are those connected with the decomposition of organic substances in the soil.

The quantity of carbonic acid in the soil air, which is always greater than that in the atmospheric air, sometimes several hundred times as great, is subject to great variations, which are due (1) to a variation in the quantity of organic matter in the soil, (2) to fluctuation in the rapidity of decomposition, and (3) to differences in the processes by which the carbonic acid can leave the soil.

Concerning the first of these reasons, investigations have shown that the quantity of free carbonic acid is proportional to that of the organic matter only when the latter is small, but that the ratio of carbonic acid to organic matter diminishes when the latter is great. The quantity of carbonic acid may remain constant when that of the organic matter varies, since a high proportion of carbonic acid in the soil air diminishes the activity of the lower organisms taking part in the processes of decay, so that with an increase of organic matter the conditions for decay become less favorable.

The degree of decomposition of the organic substances, and consequently the proportion of carbonic acid, depends principally upon the access of air, moisture, and warmth. The quantity of free carbonic acid increases, other conditions being the same, with the supply of oxygen, up to a certain low limit. This increase, however, is not directly proportional, but is progressive at first, and after passing a certain limit is less than that of the supply of oxygen. The decomposition of organic matter, and hence the production of carbonic acid, rises and falls with the quantity of water in the soil, so long as the access of air is not prevented beyond a certain limit. With an increase in temperature up to about 50° C. the intensity of the decomposition of organic matter and of the production of carbonic acid increases. The resultant action of the above-mentioned factors depends on the fact that the extent of the production of carbonic acid is determined by the minimum factor. From this it follows that the quantity of free carbonic acid, the proportion of organic matter remaining constant, is very variable, depending on the physical structure of the soil, its covering, and on the meteorological conditions. In the case of varying quantities of organic matter, its influence on the quantity of carbonic acid may be diminished or entirely eliminated if the more important factors of decomposition (water and temperature) act in the reverse direction. Further than those already given, general laws to account for the very wide variations mentioned can not be framed. In individual instances the local influences alone decide the result.

In conclusion we may note that carbonic acid can pass out from those strata where it is most copiously produced into layers above and below. Its penetration into lower layers and its escape into the atmosphere probably account for the fact that the proportion of carbonic acid is generally greater in the lower layers of the soil. The sinking of carbonic acid into lower layers and its escape into the atmosphere depend essentially on the physical structure of the soil as a whole and of its separate strata, in that the accumulation of the gas in the pores of the soil is promoted by fineness of grain structure and an increase of humidity, and *vice versa*. The influence of the quantity of organic matter and of the external factors of decomposition on the proportion of carbonic acid in the soil air may, therefore, under certain circumstances, be marked by variations in permeability. Thus a coarse-grained sandy soil, rich in humus, may contain less carbonic acid than a fine-grained soil poor in humus, because in the former case the gas will be given off to the atmosphere very much more quickly than in the latter. Such facts, in conjunction with those already adduced, justify the conclusion that the quantity of free carbonic acid in the soil does not show the intensity of the organic processes nor the quantity of organic matter in the soil.[1]

V. THE BEHAVIOR OF THE SOIL TOWARD HEAT.

As the sources of heat for the soil we must consider the heat of the sun, the heat due to chemical action and absorption of gases, and the internal heat of the earth. The heat of the sun is of primary importance, while the other factors have very slight influence.

The heat resulting from the oxidation of organic matter (decay, slow combustion) is, as a rule, insufficient to cause any considerable rise in the soil temperature. It has been found, however, that with the incorporation of organic manure into cultivated soils the rise in temperature, other things being equal, is proportional to the quantity of manure and (within certain limits) the amount of heat produced by the decomposition of the manure is proportional to the initial temperature and humidity of the soil. The greater the chemical tension and the larger the amount of easily decomposable compounds (especially those containing nitrogen) present in the material applied, the greater the amount of the heat produced, if the porosity and temperature (over 10° C.) are favorable. For these reasons the most energetic liberation of heat takes place, as a rule, immediately after the introduction of stable manure or undecomposed vegetable matter. This persists for a period dependent upon the favorableness or unfavorableness of the external conditions and the quantity and nature of the organic material, and diminishes by degrees until the temperature of the manured and unmanured soil has become the same.

Geb. agr. Phys., 1, p. 158; Ibid., 13, p. 15. F. Möller, Mittheilung aus dem forstlichen Versuchswesen Oesterreichs, 1, p. 121; Forsch. Geb. agr. Phys., 2, p. 329. E. Wollny, Vierteljahresschrift für öffentliche Gesundheitspflege, 1883; Landw. Vers. Stat., 25 and 36; Jour. Landw., 34 (1886), p. 213; Forsch. Geb. agr. Phys., 3, p. 1; 4, p. 1; 5, p. 299; and 9, p. 165.

The warming effect of the above-mentioned manures lasts from 4 to 12 weeks and amounts to 0.1 to 0.4° on an average, though only when comparatively large quantities of readily decomposable material are used and the circumstances are favorable to decomposition. From these data, and also from the fact that in most cases the amount of heat produced by the quantities of manure ordinarily used or by the decomposition of the humus already present in the soil is scarcely appreciable, it may be assumed that the source of heat in question is of subordinate significance.[1]

Of still less importance is the liberation of heat on the addition of water, or the absorption of gases and water vapor by the soil, inasmuch as the effect thus produced is of only short duration and seldom occurs under natural conditions, since the conditions are not often favorable to condensation.[2]

Very little of the internal heat of the earth is communicated to the soil, owing to the poor conductivity of the earth's crust, and the effect is approximately the same for all soils.

From the above facts it follows that the marked differences observed in the temperature of the soil are brought about only by the heat of the sun, since other sources of heat than those already mentioned do not exist. The effects of the sun's heat are modified principally by (1) the physical structure of the soil, (2) the covering, (3) the position of the soil, and (4) the course of the meteorological elements.

INFLUENCE OF THE PHYSICAL STRUCTURE OF THE SOIL.

For a proper understanding of the rather complicated phenomena connected with the warming of the soil it is necessary to consider separately the different factors concerned.

---

[1] F. Wagner, Forsch. Geb. agr. Phys., 5, p. 373.

[2] A. Stellwaag, Ibid., p. 210. J. Breitenlohner, Ibid., 7, p. 208.

The absorptive capacity and emission capacity of the soil for heat rays.—No experiments are recorded regarding the absorptive capacity of the soil for the true heat rays (invisible ultra-red) of the solar spectrum, but the absorption of the visible rays depends on the color of the soil. Assuming the behavior of the dark heat rays to be the same as that of the luminous rays, we can say that the darker the color the more the soil is warmed. The absorption of the luminous rays is of importance, because the proportion between luminous and non-luminous rays is nearly constant in sunlight, the invisible radiation amounting to only twice the visible radiation.

The color of the soil tells us nothing concerning the emission capacity for heat rays. Kirchhoff's law states that the ratio of emission to absorption is the same in all bodies, but only for rays of the same wave length at the same temperature. Soils when exposed to the sun absorb a mixture of rays of every degree of frangibility and temperature, but emit only rays of slight refrangibility (dark rays) and low temperature; therefore the rays absorbed are different from those emitted. From this it follows that emission can not be directly estimated from absorption. So far as we can generalize the results of experiments thus far made along this line, it may be said that the mineral constituents radiate heat better than the organic, and that of the former quartz radiates most perfectly. In natural soils, which generally consist of a mixture of constituents, the differences in radiation capacity are very small. Water radiates heat rays to a greater extent than any of the solid constitutents of the soil. Therefore when much moisture is present the differences which would otherwise occur in the emission of heat disappear almost entirely.[1]

The heat absorbed in evaporation at the surface of the soil.—The heat of the sun absorbed by the soil is lost partly by being communicated to and warming the lower strata of soil, and partly by being rendered latent by evaporation. Loss of heat in the second way increases and decreases, other things being equal, with the quantity of evaporation.

The heat capacity (specific heat) of the soil.—This property, like the water capacity, is most conveniently referred to the volume, and is expressed by the number of units of heat necessary to raise the temperature of a definite volume of the soil 1°, compared with the number required to raise the same volume of water the same interval of temperature, this number in the case of water being considered as unity. The specific heat of the soil in the dry state amounts to one sixth to one third that of water. Of the various soil constituents, quartz has the highest specific heat (0.2919), humus the lowest (0.1647), while clay is intermediate (0.2333). With an increase of water in the soil, the specific heat of course increases; therefore in one and the same soil the specific heat is higher in proportion to the absorptive capacity for water vapor and to the water capacity, and *vice versa.* For this reason the specific heat is greatest in humus, less in clay, and least in quartz, when the relative saturation with water is the same. In soils containing much water the specific heat is greatest when the particles are fine and compactly arranged. The specific heat is also smaller in soils with crumbly structure than in those having separate grain structure, other things being equal.[1]

[1] A. von Liebenberg, Untersuchungen über Bodenwärme; Habilitationsschrift, Halle, 1875. C. Lang, Forsch. Geb. agr. Phys., 1, p. 379. E. Wollny, Ibid., p. 43; 4, p. 327. J. Ahr, Ibid., 8, p. 397.

The conductivity of the soil for heat.—The temperature of the uppermost layer of the soil is communicated by conduction to the lower layers. The temperatures in the upper and lower layers tend to equalize themselves, but for this a certain length of time is of course required. This circumstance explains a number of phenomena noticed in studying the thermal conditions of the soil.

There is both an upward and downward movement of heat, and it is slowest in humus, quickest in quartz sand, and has an intermediate velocity in clay. Carbonate of lime and ferric oxid have a conductivity for heat intermediate between clay and quartz. In one and the same soil in the dry state the conduction of heat generally increases with an increase in the size of the particles and aggregates. Conduction increases with the proportion of stones and with the compactness of arrangement of the particles. The differences also increase, as a rule, with the quantity of water in the soil. Water increases the conductivity of a soil very considerably, and in proportion to the quantity present, other things being equal.[2]

The soil temperature observed under any given circumstances depends, in as far as it is affected by the mechanical structure of the soil, on the resultant action of all the factors just described. The causes attributable to the soil itself bear such a varied relationship to one another that no satisfactory explanation can be arrived at from average figures for observations covering long periods of time as to the individual factors in different soils. Only the variations in different periods with varying external temperature can be decided. This might be inferred from the fact that, under the same external circumstances, different kinds of soil, in spite of their very different behavior toward variations in heat, show the same yearly average, or differences of only a few tenths of a degree. This is explicable when we bear in mind that differences occurring in separate periods are of such a nature as to counterbalance one another. The thermal conditions can therefore be clearly determined only by taking into consideration the course of the soil temperature.

With a rising temperature (during exposure to sunlight by day or during warm seasons) quartz warms up most strongly of any of the soil constituents, then follow in order clay, chalk, and humus. With a falling temperature (during the night or during cold seasons) the heat conditions are exactly the reverse, inasmuch as quartz cools most quickly, humus most slowly, while clay and chalk are intermediate. The reasons for this are to be found principally in the differences in specific heat of the various constituents in the moist state and in their conductivity for heat, as described above.

In soil of the same constitution the warming depends on the nature of the surface, and the size and arrangement of the particles, as well as on the humidity.

With regard to the influence of the nature of the surface we may mention first that drying up of the top layer induces a rise in the soil temperature owing to a reduction in the evaporation throughout the mass but especially at the surface. The superposition of thin layers of a soil which easily dries up (quartz sand) has the same result. If the upper layers of the soil are stirred the temperature is lowered, because the conductivity of the dry layer, owing to the large quantity of inclosed air, is diminished and the fragments lying on top are only partially in contact with the soil below for purposes of conduction. The constitution of the soil being the same, the color has a decided influence down to comparatively great depths. During the warmer seasons, when the radiation is unhindred, the dark-colored soils are warmer. The differences in temperature in dark and light colored soils disappear more or less during colder seasons when the exposure to the sun is imperfect. This influence of color diminishes as the humidity increases, and as the other factors controlling the warming of the soil obtain preponderance. Under greater differences in the physical properties, especially those due to a higher proportion of humus and to a larger capacity for water, the influence of color may be entirely eliminated.

Regarding the warming of the soil as affected by differences in structure, it has been observed that the soil warms up during the summer and cools down during winter more strongly when the structure is coarse. The principal reason of this is that with an increase in the diameter of the particles are connected a decrease in the quantity of water and an increase in conductivity. Crumbly soils are, as a rule, warmer than powdery, but the differences are comparatively slight. On the other hand, an increase in density of the mass of the soil has a very important influence on its temperature, in that an increase of density causes a higher temperature during warmer seasons or with a rising temperature and a lower temperature during colder seasons or with a falling temperature. This difference may be explained by the fact that by the compacting of the soil its conductivity is increased, and to such an extent that the accompanying increased absorption of heat due to evaporation is for the most part eliminated. The presence of stones in the soil results in a greater capacity for heat in consequence of increased conductivity. At the same time a stony soil cools more rapidly than one free from stones when the temperature falls.

The heat conditions of the soil are dependent to quite a remarkable extent on the quantity of water present. During the warm season the temperature of the soil is generally lower when much water is present, because as the absorption of heat by evaporation increases the specific heat also increases. These differences in temperature are the smaller the more the evaporation diminishes and the increased conductivity due to greater humidity can exert its influence. They are, therefore, during the cold season smallest when the exposure to the sun's rays is slight, the air cool, and still the humidity of the air high and the top layer of soil dry. The effect of cooling due to evaporation, external conditions being the same, is the more easily eliminated and counterbalanced the less water the soil contains, the smaller its water capacity, and the more slowly it replaces by capillarity the loss of water from the surface. With regard to differences in temperature of wet and moist soils (maximum 1 to 1.5° C.), it seems unjustifiable to attribute the low productiveness of wet soils to their lower temperature.

In the freezing of water in the soil the phenomenon of supercooling may be noticed. The soil water, under the influence of capillary tension, becomes cooled by frost below its real freezing point without solidifying, but as soon as any impulse is given to its solidification it passes at once into the form of ice. The heat liberated by this change is sufficient to keep the soil at 0° C. until this heat is used up and the temperature of the soil gradually comes into equilibrium with the lower surrounding temperature. The supercooling temperature of soil water seems to be lower as the humidity decreases and as the energy with which the water is held by the soil increases. During continued frost the temperature of the soil falls faster and lower the less the humidity of the soil. Afterwards the differences in the temperature tend to disappear, or are, under certain circumstances, reversed.

The penetration of frost takes place most quickly in quartz sand, more slowly in clay, and most slowly of all in humus. When the soil thaws out its temperature first rises to 0°, and remains constant for some time before it undergoes a further rise in temperature. Thawing takes place most quickly in quartz sand and most slowly in humus, clay being, as usual, intermediate. Frost disappears most quickly when there is least moisture in the soil.[1]

INFLUENCE OF THE POSITION OF THE SOIL.

The temperature of the soil varies with a change in exposure. A southerly exposure is warmest; then easterly, westerly, and northerly exposures follow in the order named. In the course of the seasons the maximum temperature shows a fairly regularly recurring variation in a southerly exposure. In the winter months (November to April) the maximum is in the southwest, in summer (May to August) in the southeast, in autumn in the south, after which it returns toward the southwest. A southerly exposure is warmer and a northerly exposure colder the greater the inclination to the horizontal. The inclination of an easterly and a westerly exposure has comparatively less influence on the warmth of the soil, but the greater the inclination the warmer is the easterly and the colder is the westerly exposure. The difference in temperature between a northerly and a southerly exposure is considerably greater than between an easterly and a westerly. The difference in temperature between a northerly and a southerly exposure is wider the greater the inclination toward the horizontal. The angle of inclination has a much smaller influence on the differences in temperatures between an easterly and a westerly exposure. The west side is, when only slightly inclined (up to 15°), generally rather warmer than the east side, but when strongly inclined is colder.[1]

INFLUENCE OF THE COVERING OF THE SOIL.

A soil covered with living vegetation or with dead plants (leaves, straw, stable manure, wood, etc.) is warmer during the cold season and cooler during the warm season than an uncovered soil, other conditions being the same. This difference is greatest in summer and winter and least in spring and autumn. When warm periods occur in winter and cold ones in summer, the influence of the covering on the soil temperature is the reverse of that mentioned, at least in the uppermost layers. A bare soil warms up more quickly in spring and cools down more rapidly in autumn than one covered with vegetation or dead plants. Frost penetrates more slowly and to a less depth into the latter than into the former, but, on the other hand, a bare soil becomes free from frost earlier in the spring. The influence of the covering in the warm seasons is more marked as the exposure to the sun's rays is more complete, and *vice versa*. The characteristic action of vegetation is greater the denser and the further developed it is, and of other covers the thicker and more compact the layer. As regards the influence of different crops on the soil temperature, the development of the leafy parts, the closeness of planting, and the length of the period of growth are of most importance.[1]

[1] F. Kerner von Marilaun, Ztschr. österr. Ges. Meteorol., 6, p. 65; Sitzungsberichte der kaiserlichen Akademie der Wissenschaften in Wien, 1891, C Abtheilung 2a. C. Eser, Forsch. Geb. agr. Phys., 7, p. 100. E. Wollny, Ibid., 1, p. 263; 10, pp. 8, 345.

Soil coverings of mineral matter influence the temperature of the soil in different ways, according to their own thermal properties. Stones, gravel, sand, etc., when in a more or less thick and uniform layer over the soil, as a rule raise its temperature during the warmer seasons, but lower it during the cold season, when the exposure to the sun is slight. The influence of such a covering is generally more marked the darker the color and the more powerful the radiation. Soils having a high water capacity and a light color (clay, marl, chalk) have an effect the reverse of that of stone, gravel, sand, etc., when used as a covering, owing to the much greater loss of heat due to evaporation and the lower absorptive power for the sun's rays.[2]

Snow, as a bad conductor of heat, prevents rapid falls of temperature during the cold season, diminishes variations in temperature, and retards the penetration of frost. When the snow melts these conditions are usually reversed. The soil free from snow warms up more quickly, since it is generally dryer than that covered with snow. The latter also takes longer to become free from frost.[3]

INFLUENCE OF CLIMATE AND WEATHER ON THE TEMPERATURE OF THE SOIL.

The constitution of the soil being the same its temperature depends on the distribution of heat over the surface and also on certain local causes affecting the influence of the sun's radiation. The intensity of solar radiation varies with the altitude of the sun, and therefore decreases with the geographical latitude. For this reason the temperature of the soil decreases from the equator toward the poles, the decrease being more rapid as the 45th parallel is approached, after passing which it is slower. This decrease in soil temperature is, however, not uniform and proportional to the latitude, but exhibits many variations due to difference in length of exposure to the sun's rays, proportion of land and water, and local influences. The longer time of radiation in northern countries during summer causes a relative rise in temperature of the soil, without which the cultivation of the soil there would be impossible. On islands and near the coast the maximum and minimum soil temperatures are not so far apart as in regions remote from the coast. If we take into consideration also the action of numerous local influences (mechanical structure, exposure, inclination, covering of the soil, etc.), it is not surprising that the "isogeothermals" (*i. e.*, lines connecting places having the same average soil temperature) should diverge very considerably from the parallels of latitude.

The yearly, monthly, and seasonal temperature of the soil at the same latitude decreases as the altitude above the sea increases. This lowering of temperature with higher altitudes is greater in the soil than in the air, and is more noticeable in spring and summer than in autumn and winter. In spite of the greater exposure to the sun's rays in high altitudes during the summer the soil temperature is lower than on the plains, because the action of the sun's heat is shorter in duration and radiation of heat and consequent cooling during the night preponderates. Local influences (exposure and inclination, massiveness of the mountains, etc.) give rise under such circumstances to many modifications of the soil heat.

Regarding local influences, it should be noted that the condition of the atmosphere (precipitation and winds), the position and covering of the soil, the presence of bodies of water, etc., may cause numerous changes in the temperature of the soil.

The condition of the atmosphere is of importance inasmuch as the absorption of rays diminishes and the emission of rays increases as the air becomes rarefied and contains dust and water particles. Clouds and mist diminish the absorption and emission. Rain usually lowers the temperature of the soil, because the water is generally cooler than the soil, and also because the evaporation from the surface is increased by wetting. The opposite effect may be brought about in summer when the soil is covered with vegetation and is dried up by previous drought. In this case the precipitation may cause a rise in temperature owing to the improved conductivity for heat due to the moistening. Winds generally produce a lowering of temperature proportional to their velocity because they increase evaporation; and this effect is the stronger in proportion to the moistness of the soil and its capacity for replacing by capillarity the water lost by evaporation. Under some circumstances the temperature of the wind may be very important. Bodies of water may lower the temperature considerably during spring and summer without raising it in autumn and winter, and may therefore cause a moderate lowering of the average temperature of the land in the surrounding region. The influence of position and covering on the temperature of the soil has already been noted. The influence of vegetation, especially of forest growth, on the neighborhood is analogous to that of a body of water.[1]

Ebermayer, Die physikalischen Einwirkungen des Waldes, etc., 1873; Forsch. Geb. agr. Phys., 15, p. 385. J. A. Henselé, Ibid., 16, p. 357.

In conclusion, it must not be forgotten that variations in weather are accompanied by similar variations in soil temperature. It is not possible to formulate general laws on this subject, because the relationships are not only very complicated in their nature but are entirely local in character. In as far as it is possible to trace the connection between climate and soil temperature in a particular case, it has been done by K. Singer for the climate of the south Bavarian plain.[1] The results of this investigation may serve to show the conditions concerned and are therefore inserted below.

In the mild winter months, during which the precipitation is plentiful, there is no particular rise in temperature compared with the normal, but rather a fall in the soil temperature, especially in the deeper layers. Mild and dry winters have a tendency to cause the temperature to rise above the normal. The temperature of the soil during a winter of alternate frost and thaw, of which the average temperature is below the normal, shows a tendency to sink unless it is already very low. In the same way, when hard frost follows mild and wet weather in early winter even a covering of snow can prevent only to a slight extent the general lowering of the soil temperature. On the other hand, during a long and severe winter, in which the snow comes to stay in December, the variation of the soil temperature is either confined to the upper layers or does not occur at all.

A warm spring with, as is usual, a considerable amount of precipitation, causes a decided (relative) rise in the soil temperature. When a cold winter with much precipitation is followed immediately by a warm spring, the temperature of only the upper layer rises, while that of the lower layers may fall still further below the normal. In case of much precipitation the soil temperatures remain unchanged compared with the normal during the different spring months. A cold spring, which is generally accompanied by much snow, is associated, as a rule, with a decided lowering of the soil temperature, even to great depths compared with the normal. When the spring weather is cold and dry the relative lowering of the soil temperature is generally slight, if it has not been immediately preceded by periods of particularly large precipitation.

A warm summer is always accompanied by a high soil temperature or a rise. The rise is all the more noticeable when a large amount of precipitation accompanies the high temperature of the air or immediately precedes it. The rise in soil temperature is not much above the normal during the warm and dry summer months. The lowering of temperature always induced by a cool summer does not reach to great depths, scarcely to 4 meters. Those months in which this relative lowering of temperature could be detected down to 6 meters were all very wet.

A warm autumn causes, with few exceptions, a relative rise in the soil temperature. This rise is slight, and may even be changed to a fall when heavy precipitation occurs in late autumn. A low atmospheric temperature is accompanied, in the majority of cases, in autumn by an excess of atmospheric precipitation, and causes then a regular and often considerable fall in the soil temperature. In the less frequent cases of cool and dry autumn months there is, as a rule, only a very slight variation in the soil temperature.

---

[1] Beobachtungen der meteorologischen Stationen im Königreich Bayern, 11.

THE DISTRIBUTION OF HEAT IN THE SOIL.

Daily variations.—During the cooler season, when the exposure to the sun's rays is slight, the temperature of the surface of the soil runs parallel to the minimum temperature of the air, but the maximum in the upper layers of the soil exceeds that of the air during the warmer season, and all the more the greater the exposure to the sun's rays and the greater the absorptive capacity of the soil.

The daily variations of temperature are greatest in the top layers, and decrease with the depth, generally disappearing at a depth of 1 meter. Considering the fact that the conduction of heat downward is gradual, it is clear that the extremes of temperature are later in the lower strata than at the surface and in proportion to the depth. The extent of this retardation depends on the physical properties of the soil, especially the conductivity for heat. In general the influences causing variations in temperature at the surface of the soil have less effect in proportion to the depth of the layer under consideration.

Yearly variations.—The yearly temperature variations are of considerable magnitude in the upper layers, decrease with the increasing depth, and finally disappear entirely. The depth at which a constant temperature obtains, or at least a temperature unaffected by the seasons, is dependent upon climatic conditions. In the tropics this depth is about 6 meters and in the temperate zones 20 to 30 meters. All factors which moderate the extremes of temperature, for instance, nearness to the sea, soil coverings of different kinds, etc., diminish also the variations in temperature. Observation teaches that in the temperate zone the variations in soil temperature cease at a depth of about 20 meters near the coast, but at about 30 meters at a distance from the sea. In the warm season the temperature of the soil diminishes on descending, but in the cold season increases with the depth.[1]

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Paris green, composition and adulterations, B. B. ROSS (*Alabama College Sta. Bul. 58, pp. 7*).—The history and character of Paris green are discussed. According to Ehrmann pure Paris green contains 31.29 per cent of copper oxid, 58.65 per cent of arsenious acid, and 10.06 per cent of acetic acid. Analyses are given of 6 samples collected in the State and 1 from a chemical house in New York. Six of the samples showed arsenious acid ranging from 53.13 to 59.71 per cent, "and no traces of adulteration or attempts at adulteration were detected." A seventh sample, although resembling Paris green except in brightness of tint, contained no copper or arsenic. Prussian blue and chrome yellow were found, with a large quantity of inert matter, as clay, chalk, etc.

> "On taking a small portion each of Prussian blue and chrome yellow and mixing with a large quantity of clay or chalk it was found that a product corresponding almost precisely in color to the material examined could be produced, and it was found quite easy to imitate the normal shade of color of Paris green, though the brightness of tint would be lacking. It was estimated that a material of this character could be manufactured at a cost not exceeding 1 ct. per pound, while a high grade Paris green frequently costs above 20 cts. per pound, the fraudulent manufacturer being thus able to dispose of his product at an enormous profit."

The method followed at the station for determining arsenious acid in Paris green is described.

On the determination of the bromin absorption of fats gravimetrically, O. HEHNER (*Analyst, 20 (1895), Mar., pp. 49–53*).—"The present contribution is merely intended as a study and not as a proposed method, although I believe that in some cases it may be found convenient and that it may afford another factor in judging of the constitution of an oil." The process is based on the fact that if bromin is added to an oil without the intervention of a solvent, combination takes place immediately, often with a rather violent reaction, but if diluted with a suitable solvent, as chloroform, the action is moderated but equally complete.

> "I operate as follows in order to obtain the bromo compounds in a state fitted for weighing: A small, wide-mouthed fat flask is carefully weighed, and from 1 to 3 gm. of the fat to be tested introduced into it. These are dissolved in a few cc. of chloroform, and then pure bromin is added, drop by drop, until the bromin is decidedly in excess. Both the chloroform and bromin must be previously tested in a

blank experiment to make sure that they contain no appreciable residue. The flask is then heated on the water-bath till most of the bromin is driven off; a little more chloroform is added, and the mixture again heated, the chloroform vapor helping to drive out the excess of bromin. The addition of chloroform may once more be repeated. The flask and its content are then placed in an air bath regulated for about 125° C. and kept there until their weight is constant; this takes several hours. A little acrolein and hydrobromic acid escape during the drying, and the residue in some cases darkens slightly; in others a clear yellow heavy bromo oil is obtained. Drying at 100° C. does not lead to satisfactory results."

The results are given of a comparison on a number of common oils of the above process with the iodin absorption by Hübl, calculating the bromin absorption into the iodin equivalent by the factor 1.587. "In most cases the iodin figure calculated from the gravimetric bromin absorption is in satisfactory approximation to the Hübl number," but in the case of castor and linseed oils, which contain more oxygen than ordinary oils, "the figures are substantially different."

The determination of lecithin in seeds, E. SCHULZE (*Ztschr. Physiol. Chem., 20, Nos. 1 and 2, pp. 225–232; 3, p. 252*).—A reply to the criticism made by Von Bitto (E. S. R., 6, p. 270), that extraction as prescribed by Schulze (once with ether and twice with alcohol) does not dissolve all of the lecithin, but that to do this requires extraction 30 times with ethyl alcohol or 20 with methyl alcohol. Schulze insists that his method is sufficient provided the material is finely pulverized, and reports some experiments which appear to support his claim. He states further that 2 samples of methyl alcohol bought for the pure article could not be used for the extraction, since they dissolved from seeds other substances containing phosphorous besides lecithin, which were insoluble in ether, and at the boiling point dissolved small quantities of water-free sodium phosphate and potassium phosphate.

Coloring matter in California red wines, W. D. BIGELOW (*Jour. Amer. Chem. Soc., 17 (1895), No. 3, pp. 211–216*).—Ninety-four samples of California red wines were examined with the aid of the reagents commonly employed in the examination of European red wines. The reactions obtained were not always the same as those obtained with European wines; for instance, a gray, or yellowish or orange-gray precipitate or solution was sometimes obtained with reagents which are said to give green or grayish-green with French wines. On the other hand, no reactions were obtained which are said to be characteristic of wines colored with vegetable pigments.—W. D. BIGELOW.

BOTANY.

Bacteria in agriculture, A. CARON (*Landw. Vers. Stat., 45 (1895), No. 5 and 6, pp. 401–418*).—The author briefly reviews some of the more recent literature relating to the assimilation of nitrogen by the micro-örganisms in the soil.

An estimation was made of the abundance of bacteria in various soils that had been cropped with oats, barley, and rye following wheat, rye, and wheat. There were found 1.5, 2.2, and 2.7 million bacteria per cubic centimeter in the three soils. It was also found that in black fallow, a fallow on which grass had been allowed to spring up prior to plowing under, the number of bacteria increases from spring until autumn, when their maximum number is to be found.

Investigations were conducted to ascertain the vertical distribution of soil bacteria, and it was found that they decrease with the increased depth of the soil from which they were taken, there being 6 million per cubic centimeter at a depth of 20 cm. and only 1.5 million at a depth of 50 cm. in a field examined.

Examinations were made of soil in which various crops, such as grain, clover, potatoes, etc., had been grown, and it was found that where grains were grown there was a decrease in the number of soil bacteria as the season advanced, while there was a constant increase in the case of the other crops. In this the author confirms the observations of Berthelot and Winogradsky[1] that grain crops do best when they follow such crops as legumes, potatoes, etc., or fallow, not only on account of the chemical and physical condition of the soil, but also on account of the presence of greater numbers of soil bacteria, by the aid of which greater amounts of nitrogen are supplied to the growing crop.

---

[1] Compt. Rend., 116 (1893), p. 1385.

The author isolated the bacteria from soils on which wheat and clover had been grown, and also from compost, making numerous pure cultures of them. Pot experiments were made to test their influence upon the growth of oats. The pots used were 22 cm. in diameter and each received 40 cc. of a bouillon culture, and all received the same fertilizers and treatment. At maturity the plants grown in the pots receiving the bacterial cultures gave as an average 18.46 gm. grain and 29.9 gm. straw, as compared with 13.26 and 22.14 gm. from the check pots.

Additional experiments were made to test the comparative value of the different kinds of bacteria isolated, the highest yield being secured when *Bacillus 39* was used for inoculating the soil.

In 1893 some field experiments were undertaken with oats in which the seed, prior to sowing, was impregnated with the desired organism by soaking for some time in liquid cultures containing it. The yields of grain from uninoculated seed and from seed so treated were in the proportion of 100:135. In the autumn the field where the oats had grown was plowed and in the spring sown with mustard. The yields of green forage on equal portions of uninoculated and inoculated plats may be represented by the proportion 100:195.

Numerous additional experiments were conducted which in every case gave a higher total yield whenever the soil or culture medium had received an inoculation with some form of soil bacteria.

The author made no attempt to show how the bacterial inoculations influenced the greater growth and productiveness of plants growing in inoculated soil, but he thinks it probable that the isolated bacteria used in the cultures possessed the same power of assimilating free nitrogen that is claimed for ordinary soil bacteria.

Upon some properties of soils which have grown a cereal crop and a leguminous crop for many years in succession, J. B. Lawes (*Agl. Students' Gaz., 7 (1895), No. 3, pp. 65–92, pl. 1*).—On a part of a field which had grown wheat for 39 years the crop was not cut in 1883, but all the grain was allowed to fall and thus reseed the land. No weeds were removed. In the second and third years there were only a few wheat plants, some of them having slender stalks and only one or two small seeds in the ear.

Four years after this field passed out of cultivation there were found growing in it 40 species of plants, and after 8 years more there were 51 species. Leguminous plants, especially *Lathyrus pratensis*, spread and grew luxuriantly.

In striking contrast with this was the paucity of species on an uncultivated field, which, when in cultivation, had been devoted to the continuous culture of beans; when the bean crop failed red clover and barley had been grown for a few years, the clover affording large yields. The vegetation on this field, when uncultivated, consisted of a few tall tufted-growing grasses; white clover growing in a pasture did not cross the border into this field which had borne leguminous crops for so long. For the cause of the luxuriance and variety of vegetation on the plats long devoted to wheat culture and of the scant growth on the field which had long been devoted to leguminous plants the author does not present any explanation which he considers entirely adequate.

On land which for nearly 50 years had not been used for a leguminous crop, but had been devoted to a rotation of roots, cereals, and fallow, yellow trefoil made a strong effort to establish itself among the cultivated crops, and was exterminated with difficulty. "It is quite evident that when the land is kept free from leguminous plant growth matters accumulate in the soil which are highly favorable to these plants. . . . It is tolerably certain that the matter accumulated does not consist of ordinary manure ingredients."

On the distribution of assimilated iron compounds other than hæmoglobin and hæmatins in animal and vegetable cells, A. B. MACALLUM (*Proc. Roy. Soc., 57 (1895), No. 343, pp. 261, 262*).—By means of freshly prepared ammonium hydrogen sulphid the author has demonstrated the presence of iron other than the above in plant and animal cells. Whether chlorophyll contains iron is yet to be demonstrated. Some of the more important facts ascertained by the author's investigations are as follows:

(1) Iron firmly combined is a constant constituent of animal and vegetable chromatin. Another compound, less rich in iron, is found in nucleoli.

(2) The chromophilous substance in ferment-forming cells contains iron, and the cytoplasm of protozoan organisms, which also probably secrete ferments, yields evidence of the presence of a firmly combined iron compound.

(3) A firm compound is present in the chromophilous substance of the cytoplasm of fungi.

(4) Of the non-nucleated organisms, bacteria, owing to their minuteness, have, with one exception, given little evidence of the presence of an organic iron compound; but in the *Cyanophyceæ* the chromophilous portions of the "central substance" contain iron, and iron may be demonstrated in the peripheral granules formed of the so-called cyanophycin.

METEOROLOGY.

New cloud classifications,[1] A. McADIE (*Phil. Soc. Washington, Bul., vol. 13, pp. 77–86*).—The history of cloud classification is briefly reviewed, and the system of Howard, proposed in 1802 and generally adopted until within a comparatively recent period, and that of Hildebrande, Abercromby, and Köppen, as modified and recommended by the International Meteorological Conference at Upsala in 1894, are explained and criticised, as well as those of Davis and Ley. The first is unsatisfactory in "that, being based purely on appearance, no account is taken of the origin and manner of formation of the cloud."

"Clouds of very dissimilar origin may have a similar appearance. Modern meteorology demands more than a record of the appearance of the cloud. It seeks the meaning of each formation and regards the cloud as an exponent of the physical processes operating in the air and resulting in cloudy condensation. The cloud is primarily valuable not on account of its beauty, but because it makes manifest motion in the atmosphere, which is not otherwise discernible. It outlines to some degree the storm mechanism at different levels in the atmosphere. Making due allowance for the fact that the cloud does not always give the true motion of the current in which it moves, as witness the Table cloud at Table Mountain, it is still, when rightly interpreted, a most significant index of air motion. There is no sound reason why the forecaster should not derive as much information concerning the movements of the air from a cloud map as from a pressure or temperature map. . . .

"[The second] classification takes some account of the cloud's altitude; and in differentiating clouds formed by diurnal ascending currents in calm air, generally of the summer cumulus type, from the clouds formed by widespread general uplifting of the vapor, some of the nimbus formations, this classification takes some account of cloud origin. In both of these directions the new system is preferable to the old; but the criticism can be fairly made that in the matter of cloud origin the new classification does not go far enough. . . .

"In addition to the direction and relative velocity of the cloud (the only conditions which have been thus far recognized or utilized in forecasting), it is demanded of the future cloud classification that it take into account the level in which the cloud is formed and the manner of formation. Some such scheme as the following might be profitably used:

Classification of clouds.

Altitude.	Formation.			
	Cooling by contact.	Mixture.	Ascension.	Electrical and critical.
Up to 250 meters	Fogs—haze, dust, and ground fogs.		Nimbus	
500 meters		Scud		
750 meters	Nocturnal radiation	Stratus	Summer cumuli	Hail clouds.
1,000 meters		Cumulo-stratus	Cumulo-nimbus	Cumulo-nimbus.
1,500 meters		Billows		
2,000 meters				
3,000 meters			Cumulus	
4,000 meters		Cirro-cumulus	Alto-cumulus	
5,000 meters		Cirro-stratus		
Above		Cirrus		

---

[1] Read before the Philosophical Society of Washington, March 2, 1895.

"The altitudes have been kept down purposely, because half of the whole amount of vapor in the air is below us at a height of 1,800 meters (less than 6,000 ft.), and it is but fair to assume that the clouds of most importance to us in forecasting are those formed below 2,000 meters. Above 8,000 meters there is practically no water vapor. Most of our clouds are formed under the second heading (mixture), where condensation results from the mixing of two imperfectly saturated currents. Where the mixing is not thorough, but confined to the edges, we have billow clouds; but while mixture is the most common cause of cloud formation, the cloud thus formed is not apt to give heavy rain. Clouds formed under the third heading (ascension), on the contrary, do give heavy rains. Here the cooling is by adiabatic expansion, and the ideal type of this formation is the cloud of the early afternoon in the tropics, with its torrential rain. Under the fourth heading (electrical) the cloud may keep adding to itself because of a very high surface electrification, or a cloud may be in such a critical condition that, as said above, the slightest jar suffices to produce great change. It is conceivable that a cloud-burst may be a sudden change of condition. . . .

"In order to get at the cloud's true meaning we must, in addition to equipping our observers with nephoscope and cloud atlas, have systematic measurements of the cloud height. This is now done at Blue Hill, Upsala, Storlein, and Berlin by means of theodolites and double observing stations. A more direct way, and one which we think is entirely practicable, is to send apparatus up into cloudland by means of kites. This would give us the conditions prevailing at different cloud levels, and the records would not be momentary."

The use of the spectroscope and electrometer in studying clouds is suggested. It is claimed that by means of a sensitive quadrant electrometer the author has been able to "tell of the approach of the cloud while yet far off and by the changes in the potential to roughly map out the sky."

Studies of the upper air,[1] A. L. ROTCH (*Boston Commonwealth, 1895, Apr. 6, pp. 8, pl. 1*).—The composition of the air brought down from the highest levels has been shown to be identical with that at the earth's surface. The pressure is reduced one half for each 3½ miles of ascent theoretically. The temperature toward the limit of the atmosphere must be far below any temperature ever observed at the earth's surface. The history of observations on the upper air by means of balloon ascensions (29,000 ft.), by balloons without aëronauts (over 10 miles), and from the summit of mountains (23,000 ft.) is reviewed.

Measures of the highest clouds (9 miles) have been made trigonometrically at Blue Hill, Massachusetts, and also in Sweden.

"A knowledge of the movement of high atmospheric layers is of great importance for the theory of the general circulation of the atmosphere, and practically for our weather forecasts, since the forces which develop storms have their origin and sphere of action within two or three miles of the earth." Continuous observations of all the elements in the higher atmosphere can only be made on mountains, though the conditions there can only approximate those in the free air. The discussions of observations at such high stations have contributed largely to the rapid progress of meteorology. The first summit station of any importance was established in 1870 on Mount Washington, New Hampshire, (6,300 ft.). Here are experienced the severest weather conditions in the world. At present but two high-level stations are maintained in this country, at Mount Hamilton, California, and at Blue Hill, Massachusetts. The highest station in Europe is at Rochers des Bosses, 1,460 ft. below the summit of Mount Blanc.

---

[1] Read before the Boston Scientific Society, March 26, 1895.

The highest in Germany is on Sonnblick (10,170 ft.). The Eiffel tower in Paris has instruments at 980 ft. above the ground. Observations at such stations, however, can never take the place of records in the free air, and we must depend on records from balloons. The first scientific ascension was made from London by Jeffries in 1784. The instruments for making observations in balloons have recently been greatly improved. Berson last year made an ascension to nearly 29,000 ft. He found:

(1) A much more rapid decrease of temperature between 1 and 6 miles than has been assumed for winter.

(2) A rise of temperature in the morning and evening between the earth and 1 mile above it.

(3) A very feeble insolation, a great humidity of the upper strata, and a fine haze which extended to his highest point.

(4) A snowflake structure of the cirro-stratus clouds, formerly thought to be composed of ice crystals.

(5) A great increase of wind, from nearly a calm at the earth to 36 miles per hour at the average height of the balloon.

Kites have been used for determining meteorologic conditions in the atmosphere, and their use has been begun very recently at Blue Hill, Massachusetts.—H. A. HAZEN.

The high flight of the balloon "Cirrus," A. BERSON (*Ztschr. Luftshiffahrt, 1895, Feb. and Mar., p. 73*).—The author gives an account of a second high flight of the "Cirrus," September 6, 1894, and of the ascensions at the same time of the balloons "Phœnix" (70,600 cu. ft. capacity) and "Majestic" (106,000 cu. ft.). The balloon "Cirrus" reached 61,000 ft. (11.74 miles), and brought back a temperature record of −89° F. (−67° C.) at the highest point. Its velocity was 83 miles per hour toward the ENE. It was not found till the last of September, near Wilna, in Russia. The "Phœnix" reached a little over 20,000 ft. and moved at about 38 miles per hour at an average height of 15,000 ft. The lowest temperature was −15° F. (−26° C.). The diminution in temperature for the "Cirrus" was 2.4° F. in each 1,000 ft. of height (44° C. in 100 meters), and that of the "Phœnix" was 4° F. in 1,000 ft. (.73° C. in 100 meters). This is an extraordinary difference and is due in large part, if not wholly, to the increased heat experienced at the very highest point from insolation, although it is highly probable that the temperature does diminish at a slightly less rate in Europe at the higher elevations. The "Majestic" failed to reach any high altitude.

Such experiments, though giving us meager information of the higher regions, are of the greatest value. If it be true that our cold and hot waves extend up to the limits of our atmosphere and are of cosmical origin, then it is of the greatest importance that conditions in them at high levels be observed.—H. A. HAZEN.

Droughts and famines in India, J. ELIOT (*U. S. Dept. Agr., Weather Bureau Bul. 11, pt. 2, Rpt. Internat. Meteorolog. Congress, 1893, pt. 2, pp. 444–459, pls. 2*).—This is a most interesting and exhaustive treatment of all the facts known regarding these terrible visitations. During 122 years there have been 17 famines. Statistics of the 8 intense famines are given, with loss of life and property, or expenditure of money to give relief.

The areas most liable to drought are chiefly in the tropical belt, where the rains are periodic. Prolonged droughts are more frequent in India than anywhere else in the world. The meteorologic features of the Indian monsoon area may be divided into two periods—the northeast monsoon of dry land winds, from January to May, and the southwest monsoon of humid sea winds, from June to December. The southwest monsoon air circulation is caused, at first, by the formation of a low pressure area over northern India in April and May because of a rapid rise in temperature. It is a breaking down of the southeast trades at the equator and an adaptation of their circulation to the changed conditions at the north. The maintenance of the new order is due to a self-contained energy liberated by rainfall rather than to a continuance of the hot weather conditions in the north. The greater part of the rainfall of India (37 in., or 90 per cent.) occurs during this southwest monsoon. Just before this wind begins northern India is one of the hottest and driest areas in the world. Occasionally maximum shade temperatures of 120° and 124° are registered. The relative humidity often falls below 20 per cent, and 1 per cent has been recorded. The variation of rainfall is greater than in any other country. In Sinde the average is 5 in. per year, and in the Khasia Hills there are 500 in., which is the greatest in the world. The range from year to year is very great; at Kurrachi, 0.47 in. in 1872, and 28 in. in 1869; at Jacobabad in 36 years, least 0.72, greatest 12.05 in.

There are three zones of rainfall in India: (1) The arid zone, with less than 15 in. rain in a year. Here cultivation is dependent on irrigation and there are practically no famines. (2) The dry zone, with 15 to 35 in. of rain. Rain sufficient in average years, but prolonged drought leads to great scarcity. (3) The moist zone, with rain 35 to 500 in. It is a singular fact that the rain is most variable where it is smallest in amount and most regular where it is greatest; hence this zone has no famines.

Favorable conditions for crops are as follows: (1) For cold weather crops (wheat, barley, pulse, etc.) a moderate rain in October, to fit the ground for plowing and in order that the moisture may germinate the seed. Occasional light showers, more especially on the higher lands, in order to develop the grain. (2) For hot weather crops of rice, heavy burst of rain for planting, moderate rain during growth, and a burst of rain to fully insure the growth of the ear. (3) For hot weather crops of millets, etc., rather heavy rain at first and occasional rains afterwards are best suited. Breaks of three or four weeks, especially if accompanied by dry, hot winds, are very injurious, and if protracted, fatal.

In north India famine is due either to the failure of two crops in succession, for example, the rain crops (millets and rice), and the cold weather crop, or to the complete failure of one crop after a series of poor seasons.

In the Deccan they are usually due to a more or less complete failure of a southwest monsoon rain throughout, following one or more bad seasons.

In the rice-growing districts the cause is usually an abnormally early end of the southwest monsoon rains.—H. A. HAZEN.

Meteorologic work in Australia, C. TODD (*Adelaide: pp. 25, pl. 1*).—This important paper describes in detail methods and results of meteorological inquiry in Australia. There are given in 7 charts types of weather selected from a larger number, and it is stated that these charts have been sufficiently studied to show what resulting weather is likely to follow, as determined from previous experience. These charts are distributed to all the stations. After the telegrams have all been received on any day and the new chart constructed, the proper type weather map can easily be found which corresponds with this new chart. The only expense then consists in telegraphing to each station the number of the chart which should be displayed for that type.

There is a ridge of high pressure which passes over the extra-tropical or temperate parts of Australia. This is made up of long loops or "highs," being broken up at times by the advance of "lows" from the tropics and northerly extensions of V-shaped low areas from the south. The position of this ridge in winter is 29 or 30° south latitude. North of this ridge are the dry southeast trades, while to the south there is a prevalence of dry northerly winds, varied by strong west and southwest winds as coastal lows pass from west to east, with rain and squalls. On the east coast winter winds are from the west. This wall or ridge plays a very important part in Australian climate. If this lies well to the south then south Australia is dry, while to the north there are frequent rains. If the wall is in the north these conditions are reversed. About 43 high areas pass during the year, with a velocity of about 17 miles per hour. The movement of low areas is much more marked and regular, there being about 60 per year, with a velocity of 25 miles per hour.

Since the interior of Australia is under high pressure, with dry southeast winds, it is often subject to severe droughts, more or less prolonged. The driest portion is in a belt of country from Lake Eyre, or about latitude 30°, to near the northwest coast, which is swept nearly all the year by the southeast trade wind. The climate of the eastern half is more favorable, owing to the more southerly sweep of the monsoon rains. The following is the experience in the past: In 13 years, with the summer pressure above and temperature below normal, the following winter rain was below the average 9 years, above it but once, and exactly average three times. In 9 years, with summer pressure and temperature the opposite of the above conditions, the winter rain was above the average seven times; below only once, and just average once. In other words, "Summer cool, with high pressure; winter dry. Summer hot, with low pressure; winter wet."

The question of seasonal or long range weather forecasts has been seriously considered. The importance of reliable forecasts to the farmer is undoubted, but they must be reasonably accurate and based on positive knowledge or they will be treated with contempt. Long range forecasts are possible only after "the accumulation and intelligent discussion of the necessary data and the correlation of weather conditions over considerable areas of the earth's surface."

> "India is the only country which has attempted anything like a systematic issue of seasonal forecasts. These are mainly based on the amount of snow falling during the previous winter on the Himalayas, and the general character of the weather in India during the five or six months preceding the setting in of the southwest monsoon; the chief objects of the forecasts being to give some idea of the probable rainfall during the ensuing monsoon."

A more uniform publication of observations to enable a better study of the records, and also a fuller discussion of these records year by year is urged. There is also great need of normal isobaric and isothermic charts for each month and the year.—H. A. HAZEN.

The climate of Cordova, Argentine Republic (*An. Ofic. Meteorol. Argentina, vol. IX, Buenos Ayres, pt. I, 1893, pp. 678; II, 1894, pp. 491, pls. 25*).—Of all the South American States, the Argentine Republic is the most progressive in the organization of a climatological system. The above-named publication of nearly 1,200 large quarto pages in 2 parts is devoted, with the exception of a few pages of annual report, entirely to statistics and discussions relating to the climate of one locality. Part 1 contains the records made at Cordova from 1872 to 1892, expressed in daily, decade, monthly, and annual means. From January, 1889, to the close of 1892 the hourly values are recorded. Part II contains the discussion of observations recorded in part I and a record of observations for 1893. Some of the most general results relating to temperature of the air, rainfall, and evaporation for the period from 1873 to 1893 are as follows: *Temperature* (degrees C.)—maximum 41.8, minimum 8.9, average 16.7; *rainfall* (mm.)—maximum monthly 116.5, minimum monthly 4.1, total 703.1; *evaporation* (mm.)—exposed evaporimeter 64.8, protected evaporimeter 31.4.—O. L. FASSIG.

Magnetical and meteorological observations made at the Government Observatory, Bombay, in the year 1893 (*Bombay: 15 (1894), No. 15, pp. 12*).—This volume is the thirty-second of the series, extending the record from 1845 up to 1893. Magnetical and meteorological observations are taken daily at 6 and 10 a. m. and at 2, 6, and

10 p. m., at which time the general atmospheric conditions are noted. Automatic records by magnetographs, barograph, thermograph, pluviograph, and anemograph are made.

The mean annual temperature for 1893 was 78.9° F.; greatest mean daily temperature, 86° (April 16); least mean daily temperature, 68.1° (February 8); maximum temperature, 92.1° (April); minimum temperature, 59.8° (February). Total rainfall, 64.63 in.; number of cloudy days, 118, and greatest daily fall of rain, 4.98 in. (June 20).—O. L. FASSIG.

Origin of cold waves, H. A. HAZEN (*Monthly Review Iowa Weather and Crop Service, 6 (1895), No. 3, pp. 4, 5*).—Data in support of the theory that cold waves originate in the upper region of the air.

On the first mercury thermometer, MAZE (*Compt. Rend., 120 (1895), No. 13, pp. 732, 733*).—The invention of the mercury thermometer is attributed not to Fahrenheit, but to Bouillian, who in the latter part of March, 1859, made comparative observations on an alcohol thermometer and on a mercury thermometer.

On an old French series of thermometric and meteorological observations, MAZE (*Compt. Rend., 120 (1895), No. 13, pp. 731, 732*).

Meteorological record for January and February, 1895 (*Massachusetts State Sta. Bul. 57, p. 1*).—Notes on the weather and a brief summary of observations on temperature, precipitation, and wind movement.

Meteorological observations at Massachusetts Hatch Station, C. D. WARNER and F. L. WARREN (*Massachusetts Hatch Sta. Met. Buls. 73–75, pp. 4 each*).—Daily and monthly summaries of observations during January, February, and March, 1895, with general remarks on the weather of each month.

Monthly Weather Review of the Nebraska Weather Service, 1894 (*Nebraska Sta. Bul. 37, pp. 96, figs. 52*).—Summaries for each month of 1894 of meteorological observations by the State Weather Service coöperating with the Weather Bureau of this Department, accompanied by outline maps of the State showing isotherms, direction of the wind, and precipitation, and charts recording velocity of wind, temperature, pressure, humidity, and precipitation, as shown by self-registering instruments at the station.

Meteorology for 1893, R. D. NEWTON (*New York State Sta. Rpt. 1893, pp. 718–733*).—This includes tables showing precipitation by months since 1882; wind record for 1893; sunshine records for 1893; a summary of sunshine records, May 1, 1885, to January 1, 1894, and daily readings of maximum, minimum, and standard air thermometers.

North Carolina weather during January and February, 1895, H. B. BATTLE, C. F. VON HERRMANN, and R. NUNN (*North Carolina Sta. Weather Service Bul. 64, pp. 1–16, maps 2; 65, pp. 19–32, maps 2*).—The usual records of observations.

WATER—SOILS.

Contributions to the study of the reclaimed marshes of the region of Médoc, France, F. BERTHAULT and J. CROCHETELLE (*Ann. Agron., 21 (1895), No. 3, pp. 122–134*).—This is an account of an investigation, including observations on crops and system of culture and physical and chemical analyses of soils of the reclaimed lands along the left bank of the Gironde estuary in the region of Médoc. These lands are protected on the west from the violent and salt sea winds by sand dunes which have been covered by forest growth and other vegetation, while the waters of the estuary are kept out by dikes and the soil is drained by numerous ditches and canals. Occasionally, however, the salt water breaks through the dikes, flooding the land and making it unfit for cultivation for several years.

In a study of the causes of the sterility thus produced the authors found that when soils which had thus been flooded contained 0.5 per cent of salt the growth of the ordinary field crops was seriously retarded, but that with 0.2 per cent cereals grew normally. It was further observed, however, that in soils of this region, termed saline and abandoned for that reason, sterility was sometimes due to a deficiency of phosphoric acid and to slow nitrification resulting from imperfect cultivation.

On the composition of drainage waters, P. P. DEHÉRAIN (*Compt. Rend., 120 (1895), No. 13, pp. 701–706*).—An account is given of observations in the same line as those reviewed in previous numbers of the Record.[1] Comparing the results obtained in 1893, which was a year of poor crops, with those obtained in 1894, a season of good crops, it was found that drainage water was more abundant and much richer in 1893 than in 1894. The poverty of the waters in 1894 is attributed to the vigor of the plants, which by means of their numerous roots completely assimilated the nitrates. The diminished amount of drainage was due to the vigorous leaf growth, which returned to the atmosphere all of the water supplied by precipitation except during wet periods. Abundant drainage was obtained only during the winter, while during the summer no water passed off in the drains.

It is calculated that the wheat crop of 1894 per hectare contained 91 kg. of nitrogen and in 1893 only 44.2 kg., but in 1893 the soil lost 49.7 kg. of nitric nitrogen in the drainage water, while in 1894 the loss from this source was insignificant. The total amount of nitrogen removed from the soil in the good season of 1894 was therefore 91 kg., as against 93.9 kg. in the bad season of 1893.

Further experiments by the author confirm previous conclusions that fallow soils lose much more nitrogen in the drainage than those covered with crops, and emphasize the importance of planting autumn catch crops.

The more important results obtained on 20 vegetation boxes left bare and bearing various crops (grapes, sugar beets, wheat, and oats) are given in the following table:

Losses of nitric nitrogen in drainage waters.

	Loss per hectare.	Ratio of drainage to rainfall.
	Kg.	
Bare soil:		
1893–'94	101.60	4.5
1894–'95	79.80	5.5
Soil bearing crops:		
1893	33.25	7.6
1894	.20	135.0

---

[1] E. S. R., 6, pp. 353, 491.

Attention is especially called to the facts that the losses from covered soil were much greater in 1893 than in 1894, and that both the losses and the ratios of drainage to rainfall were higher than those reported by Schlössing (see below).

The loss of nitrogen in drainage water, T. SCHLÖSSING (*Compt. Rend., 120 (1895), No. 10, pp. 526–530*).—The author maintains that the studies on this subject, made for the most part in vegetation pots or boxes, for obvious reasons, have given results much in excess of the truth, and that examinations of the water of streams draining a given area will furnish a more accurate measure of the loss of nitrogen in drainage. Determinations of nitric nitrogen in the waters of the Seine, Marne, Yonne, and Oise are reported, and estimates based on the results are given which indicate that each hectare of soil in the Seine basin loses 4.2 kg. of nitric nitrogen if one sixth of the rainfall escapes in the drainage, 6.44 kg. if one fourth escapes, and 8.48 kg. if one third escapes. It is stated that while these results do not warrant definite conclusions they nevertheless indicate that the losses of nitrogen in the drainage water are not so important as has been supposed.

A chemical process of purifying water, F. BORDAS and C. GIRARD (*Compt. Rend., 120 (1895), No. 12, pp. 689–691*).—In this process slightly more permanganate of lime than is necessary to oxidize the organic matter is added to the water and the excess of permanganate reduced and the color destroyed by manganese dioxid.

Soil temperatures (*Nebraska Sta. Bul. 37, pp. 96, charts 12*).—Charts are given showing soil temperatures at the station at depths of from 1 to 36 in. during each month of 1894.

Soil temperatures, R. D. NEWTON (*New York State Sta. Rpt. 1893, pp. 734–739*).—Tridaily readings of soil thermometers at depths of 1 to 18 in. are recorded for 6 months (May to October) of 1893.

FERTILIZERS.

The influence of oxid of iron and alumina in the reversion of superphosphate, A. SMETHAM (*Jour. Soc. Chem. Ind., 14 (1895), No. 2, pp. 112–114; 3, pp. 242, 243*).—The chemical changes which take place in the reversion of the monophosphate of lime in superphosphates to dibasic phosphate are explained, and it is claimed that "where fine grinding is the rule, and where the mixing is complete, and the acid usually in excess of that required for the transforming of the tribasic phosphate to monobasic form, reversion due to the formation of a dibasic phosphate is seldom, if ever, met with." When, however, as is usually the case, the original phosphate contains an appreciable amount of oxid of iron or alumina it is found that the solubility of the phosphoric acid of the superphosphate diminishes to a considerable extent on keeping, any quantity over a very small percentage of oxid of iron and alumina being considered "as reverting double its weight of soluble phosphate."

In studying the relative effects of oxid of iron and alumina in causing reversion the author selected samples of known history and character and determined (1) the effect on the solubility of the phosphoric acid of adding known quantities of the oxid of iron or alumina, and (2) the solubility of the latter at different periods.

In a superphosphate containing 25.97 per cent of soluble phosphoric acid and 3.21 per cent of insoluble phosphoric acid the addition of an amount of sulphate of iron containing Fe_2O_3 equal to 1.36 per cent of the superphosphate resulted in the immediate reversion of 1.86 per cent of acid, 2.39 per cent in one year, and 2.42 per cent in 15 months. Aluminum sulphate was added to the same superphosphate in an amount furnishing Al_2O_3 equal to 1.1 per cent of the whole mixture, but the results were much less marked than in the case of the addition of iron. The immediate reversion was 0.17 per cent, at the end of a year 0.83 per cent, and at the end of 15 months 1.02 per cent. An examination of other samples of superphosphate showed that reversion was due principally to the oxid of iron present.

A superphosphate which showed when made 36.5 per cent of soluble phosphoric acid contained at the end of a year 38.19 per cent, and it is noted that in case of high percentage superphosphates there is frequently an increase rather than a decrease of soluble phosphoric acid on keeping.

"A review of the facts already obtained makes it pretty certain that there is a wide difference in the behavior of oxid of iron and alumina in the manufacture of superphosphate. The first, for practical purposes, seems to revert phosphate in what may be called theoretical proportions, viz, 160:310, or as nearly as possible 2 parts of phosphate to 1 of oxid of iron, while the alumina, which, if acting in the same manner as oxid of iron, would revert three times its weight of phosphate, at most seems to cause a retrogression of its own weight. It has long been known that superphosphate manufactured from Florida phosphate increases in the percentage of soluble phosphate instead of retrograding, and as this phosphate contains scarcely any oxid of iron, but 2 to 3 per cent of alumina, it was difficult to understand this behavior. The foregoing results, however, explain the matter.

"Under these circumstances, and especially as many of the phosphates now coming into the market contain alumina in larger proportions than oxid of iron, it appears to me that there is pressing need for a revision of the terms of the contracts on which phosphates are usually sold, and for a differentiation of oxid of iron and alumina in the analysis upon which the sales are made."

In the discussion following the reading of this paper its essential conclusions were confirmed by several other analysts.

Farmyard manure (*Agl. Jour. Cape Colony, 8 (1895), No. 5, p. 111*).—In trials of covered and uncovered manure on potatoes and wheat during 2 years the results strongly favored the covered manure.

Utilization of the refuse bones of the farm, L. GRANDEAU (*Jour. Agr. Prat., 59 (1895), No. 15, pp. 527, 528*).

Nitrate deposits in South Africa (*L'Engrais, 10 (1895), No. 15, p. 352*).—The discovery of nitrate deposits in caves near Prieska at an elevation of 3,000 to 4,000 ft. is noted. The material is composed generally of nitrate of lime, but sometimes contains 95 per cent of finely crystallized nitrate of potash. The nitrates are believed to be formed from the accumulated excrement of rabbits, which breed in numbers in that locality. An English company has been organized for the exploitation of the deposits.

What is Thomas slag and how shall it be used? M. MÄRCKER (*Ztschr. landw. Ver. Hessen, 1895, No. 12, pp. 90–92; Wochenschr. pom. ökon. Ges., 25 (1895), No. 7, pp. 79–81; Königsberger land- und forstw. Ztg., 1895, No. 11*).

Note on the decomposition of phosphates containing fluorin, S. FEITLER (*Dingler's polytech. Jour., 294, pp. 188, 189; abs. in Jour. Soc. Chem. Ind., 14 (1895), No. 3, p. 286*).

Commercial fertilizers (*Kentucky Sta. Bul. 52, pp. 83–116*).—Analyses and valuations of 11 official samples of fertilizers (sent to the station by manufacturers) and 87 samples sent by farmers or taken by deputy inspectors are tabulated and discussed.

Inspection and analyses of commercial fertilizers sold in Maryland, H. B. McDONNELL, ET AL. (*Maryland Sta. Bul. 30, pp. 3–54*).—Explanations of terms used in fertilizer analyses, notes on guaranties and valuation, a list of manufacturers licensed to sell fertilizers in Maryland in 1894, text of the State fertilizer law, and tabulated analyses and valuations of 362 samples of fertilizing materials.

Analyses and valuation of manurial substances (*Massachusetts State Sta. Bul. 57, pp. 6–8*).—A schedule of trade values for 1895 is given, together with tabulated analyses of 22 samples of fertilizing materials, including ashes, cotton-hull ashes, ground bone, cotton-seed meal, guano, sheep fertilizer, and peat.

Commercial fertilizers, P. COLLIER and L. L. VAN SLYKE (*New York State Sta. Rpt. 1893, pp. 181–204, 497–539*).—Text of the State fertilizer law, notes on the agreement of actual and guaranteed composition, valuation, and home-mixing, and tabulated analyses of 330 samples of fertilizers, with a statement of the amounts of different kinds of fertilizers reported as sold in the State during the year ending November 1, 1893. The aggregate amount was 106,520 tons.

Fertilizer analyses, H. B. BATTLE (*North Carolina Sta. Spec. Bul. 24, pp. 14; 25, pp. 16*).—These bulletins give a digest of the State fertilizer laws, explanations of terms used in analysis, notes on valuation, freight rates, and tabulated analyses and valuations of 313 samples of fertilizers.

Analyses of commercial fertilizers, J. L. HILLS and B. O. WHITE (*Vermont Sta. Bul. 45, pp. 3–8*).—A schedule of trade values for 1895, notes on valuation, tabulated analyses of 15 samples of fertilizers, and a list of manufacturers paying license fees as required by law.

FIELD CROPS.

Field experiments with corn, 1894, F. D. GARDNER (*Illinois Sta. Bul. 37, pp. 24*).

Synopsis.—Accounts are given of experiments in the following lines: (1) Test of varieties, (2) time of planting, (3) thickness of planting, (4) continuous cropping *vs.* a rotation of crops, (5) cross fertilization, (6) detasseling, and (7) listing. The results of these and previous experiments at the station favor (1) the medium maturing white varieties, (2) planting in May, especially from the 11th to the 18th of the month, (3) thick planting, (4) rotation of crops, and (5) cross fertilization. The yield of detasseled corn in 1894 was 13 per cent greater than that not detasseled, although in 1891 and 1892 detasseling had exercised no marked effect on the yield.

The experiments in 1894 were in continuation of those reported in Bulletin 31 of the station (E. S. R., 6, p. 29). They were conducted on dark colored, fertile prairie soil in hills 3 ft. 8 in. apart each way.

Varieties (pp. 1–16).— The test of varieties occupied 84 fortieth-acre plats, and the results are given in detail in tables, summaries, and general notes. Mixtures of 2 and 4 varieties gave larger yields in 1894 than single varieties, though mixtures did not afford the larger yield every year. The height of stalks and size of ears increased with lateness of maturity. Of 13 varieties tested during 5 years Boone County White gave the largest yield, 71.5 bu. per acre, followed by Burr White, 61.9 bu., and Leaming, 60.7 bu. per acre. The medium maturing varieties averaged for 7 years 65.2 bu., the late varieties 58.8 bu., and the early varieties 55.5 bu.; the yellow varieties averaged for 7 years 60.3 bu. per acre, and the white varieties 63.2 bu.

Time of planting (pp. 16–18).—Burr White was planted at intervals of a week from April 6 to June 22; the average yield for 7 years was greater from planting from May 11 to May 18. The variation was slight for the dates between April 27 and May 25.

Thickness of planting (pp. 18, 19).—In 1894, 2, 3, 4, and 5 kernels were planted in hills 3 ft. 8 in. apart each way; the yield from planting 2 kernels was 40.2, 3 kernels 46, 4 kernels 49, and 5 kernels 48 bu. per acre. In another field with 3 kernels per hill the yield was 44.6, and with 4 kernels 50.5 bu. per acre.

Continuous corn cropping compared with rotation of crops (pp. 19, 20).—Corn grown in rotation with oats and clover yielded 40 per cent more than corn in continuous culture. Tabulated data give the yields in detail.

Cross fertilization (pp. 19, 20).—From cross fertilized plants seed was selected in 1892 and again in 1893, the latter, together with both parent varieties, being used for the crop of 1894. The average increase in yield in 1894 from the cross fertilized seed was 12 bu. per acre.

Detasseling (pp. 21–23).—The tassels were removed from stalks on alternate rows; on the detasseled rows the yield was 56.5 bu., and on those not detasseled 50 bu. per acre. The increase in yield was greater where the tassels were removed early than where they were removed later. Contradictory results secured in previous years and at other stations are briefly noted. "If an increase in grain is secured by detasseling, it is most likely to be on poor soil or in dry seasons. It seems that the injury done the plants sometimes reduces the yield."

Corn, W. W. COOKE and F. L. WATROUS (*Colorado Sta. Bul. 30, pp. 12–21, 24, 25*).—Eight varieties of flint corn and 14 of dent corn were tested. The average yield of dry matter per acre was with the small flint varieties 2.70 tons, with the large flint varieties 2.51 tons, with the small dent varieties 3.60 tons, and with the large dent varieties 3.38 tons. The largest yield of corn, 43 bu. per acre, was made by the small dent varieties Huron and White Pearl. The earliest variety was a small flint, Will 70-Day Gehu, which yielded 37.8 bu. of corn per acre, and which seems adapted to many portions of the State which are generally regarded as too cold for corn.

Red Cob corn cut September 29 afforded no more dry matter per acre than when cut September 5. "The figures seem to show that in this part of Colorado, so near the foothills, corn can not be depended on to grow after the first week in September, and such varieties should be chosen as will reach the glazing stage by that time."

Coöperative soil tests with corn, A. J. BONDURANT (*Alabama College Sta. Bul. 59, pp. 23*).—This is a report of coöperative tests in 23 localities. A fertilizer consisting of equal parts of cotton-seed meal and superphosphate, applied to corn at the rate of 1,000 lbs. per acre, resulted in a financial loss of $2.29 per acre. The author assumes that peas planted between the corn rows would have yielded in the same proportion as the corn, and on this basis calculates a profit of 71 cts. per acre in favor of fertilizers.

The loss of corn fodder in drying, W. W. COOKE and F. L. WATROUS (*Colorado Sta. Bul. 30, pp. 23, 24*).—In 1893 the loss of dry matter in field curing corn was fully one third. In 1894 corn was cured in shocks, each containing about 500 lbs. of green fodder, in small shocks, and in a thin layer on the ground.

"So far as could be told by the eye there had been no loss. The fodder had cured in nice shape, and the stalks on the inside of the bundles retained their green color, with no sign of molding or heating. And yet the large shocks had lost 31 per cent of their dry matter, or feeding value, the small shocks 43 per cent, and the corn spread on the ground 55 per cent.

"On breaking or cutting the stalks these losses were explained. The juice was acid, and there was a very strong acid odor, showing that an active fermentation was taking place in this seemingly dry fodder."

Flax for seed and fiber, C. R. DODGE (*U. S. Dept. Agr., Farmers' Bul. 27, pp. 16*).—The author shows that good seed and salable fiber can be produced from the same plant. He points out the need of scutch mills, and advises a threefold division of labor in establishing an American flax fiber industry, viz, the growing of the crop by the farmer, the retting and scutching by the purchaser or factor, and the spinning and weaving by the manufacturer.

Other topics treated are soil selection and preparation, fertilizing, rotation, kind and amount of seed, meteorological considerations, and harvesting seed and fiber.

Experiments with foreign seeds, P. H. MELL (*Alabama College Sta. Bul. 60, pp. 27-32*).—Analyses are given of *Eleusine corocana* and *Paspalum scorbiculatum*, two foreign plants which proved satisfactory for forage. Japanese buckwheat, flat pea, and soja beans succeeded on the station farm. Sugar beets, damaged by nematodes, contained 8.5 to 11.4 per cent of sugar. Chick-pea, sesame, and green gram (*Phaseolus mungo*) were grown, and the last-named plant matured earlier than the garden pea.

A contribution to the study of hops, A. LEPLAE (*Contribution a l'étude du houblon. Bruxelles: 1895, pp. 84, figs. 72*).—This publication is chiefly devoted to the methods of drying hops and to the construction of hop kilns. Chemical and mechanical analyses of dried-hops, qualities desired in hops, and methods of harvesting also receive attention.

Although the cones bearing seeds do not contain less lupulin than the unfertilized flowers, they are not favorably regarded by brewers in

Belgium. However, the entire destruction of the male plants so as to prevent fructification not only diminishes the yield, but delays the development of the cones.

The author favors curing by means of flue heat rather than with open fires, because the former conserves the natural aroma, reduces the danger from fire, and permits the easy regulation of temperature and draft. He states that the initial temperature of drying should not exceed 95° F., and that the temperature should never rise above 104° F. A temperature too high causes the loss of essential oil, imparts a distinct and undesirable odor, and injures the appearance of the product.

He regards sulphuring as indispensable, as it destroys fungi and thus permits the easier conservation of hops, without, as he states, endangering the health of consumers of beer. Kaemmerer had shown that hops took up about 0.48 per cent of their weight of sulphurous acid, of which, however, only one fourth or one fifth was retained permanently, the remainder being dissipated in about 4 weeks.

The author regards 1 to 1½ lbs. of sulphur as sufficient for 100 lbs. of hops, if the sulphur is burned early in the process of drying.

Oats, A. C. MAGRUDER (*Oklahoma Sta. Bul. 16, pp. 33–40*).—With the Jensen hot-water treatment for smut the yield was increased 1.41 bu. per acre. When the seed bed was rolled twice the yield was slightly reduced. Broadcasting afforded a smaller yield than did the press drill. Subsoiling reduced the yield on alkali land. Fifty varieties, of which the seed was grown in Oklahoma or farther south, averaged 13.8 bu. per acre; 34 varieties from the States farther north 12.4 bu. The variety Lincoln is recommended. Deep fall plowing gave a larger yield than deep spring plowing or shallow fall plowing. Other subjects briefly mentioned are amount of mixture between varieties, quantity of seed, and continuous culture of oats without manure.

Varieties of potatoes, F. W. RANE (*West Virginia Sta. Bul. 38, pp. 32–38, 46–50, figs. 3*).—Of 36 varieties tested on single or duplicate rows 75 ft. long, the following are recommended: American Wonder, Rural New Yorker No. 2, Great Divide, Superior, Crown Jewel, Early Everitt, and Maggie Murphy.

Potato experiments, R. H. MILLER and E. H. BRINKLEY (*Maryland Sta. Bul. 31, pp. 73–82*).—The experiments consisted of tests of varieties, green manuring, spraying, distance, methods of cultivation, and amount of seed. When crimson clover was plowed under as a green manure early in May the yield increased by more than 19 bu. per acre. Spraying with Bordeaux mixture afforded a larger yield than the untreated plat, and when spraying was begun early the yield was further increased. Distances of 14½ by 30 in. afforded a larger yield than distances of 12 by 36 in. Deep cultivation, ridge culture, and cultivation continued late in the season proved slightly advantageous. Small whole seed potatoes afforded a larger profit than large whole potatoes and cuttings.

Determination of sugar in beets, cornstalks, and sorghum, P. COLLIER (*New York State Sta. Rpt. 1893, pp. 176–178*).—The percentages of sugar in 8 varieties of beets, in the stalks of 3 varieties of sweet corn, and in sorghum are given. The juice of the cornstalks averaged 11.4 per cent of total sugar, "or nearly 92 per cent of that present in the sugar cane juice." The weight of topped and stripped stalks of sweet corn growing on an acre is estimated at 9,257 lbs., but the quantity of juice is not reported.

The composition of wheat grown on saline soil, BERTHAULT and CROCHETELLE (*Compt. Rend., 120 (1895), No. 12, pp. 691–693*).—In Algeria it frequently occurs that hot weather early in June causes vigorous wheat plants on certain kinds of soil to lose their green color, the heads drying and the grain becoming shriveled and hard. The crop is largely reduced. This trouble occurs on saline soil. A sample of such soil contained 0.64 per cent of potash, 0.26 per cent of soda, and 0.014 per cent of chlorin. The nodes and the middle internodes of wheat plants affected as above were covered with a deposit of chlorid of potash. Chlorid of potash was found to be most abundant in the nodes, the dry matter of which contained 0.718 per cent of this salt, while the dry matter of the entire plant contained 0.125 per cent.

Farm notes for 1894, W. W. COOKE and F. L. WATROUS (*Colorado Sta. Bul. 30, pp. 3–12*).—Six varieties of wheat, 15 of oats, 8 of barley, 4 of buckwheat, 6 of millet, and 5 of beets were tested. Polish wheat, also incorrectly known as Mammoth Spring rye, yielded under unfavorable conditions 25 bu. of grain per acre. It is recommended as a stock food, but needs first to be ground. Of the varieties of barley tested the California is recommended, on account of its productiveness and drought-resisting qualities. The effects of tankage and bone meal were tested on potatoes, with inconclusive results.

Yellow millo maize, white millo maize, evergreen broom corn, Japan broom corn, African millet, Jerusalem corn, Egyptian corn, red Kaffir corn, and white Kaffir corn were grown; yellow millo maize ripened earliest and afforded the largest yield of forage and of grain.

Flat pea (*Lathyrus sylvestris*) and sachaline (*Polygonum sachalinense*) showed no very desirable qualities. Rape yielded very heavily, the smallest yield on any plat being 22 tons of forage per acre.

Alfalfa, its characteristics, cultivation, worth, uses, and adaptability to Kansas (*Rpt. Kansas Bd. Agr. 1895, Mar. 31, pp. 3–43*).—This is an abridgment of a previous report on alfalfa culture in the West.

Jerusalem artichoke (*Agl. Jour. Cape Colony, 8 (1895), No. 5, pp. 109, 110*).—Notes on the culture, yield, and value.

Sprouting beet seed before sowing (*Landw. Centbl. Posen, 33 (1895), No. 13, p. 74*).

Cañaigre, A. E. BLOUNT (*New Mexico Sta. Bul. 14, pp. 37–44*).—This is a general discussion of the subject, the topics treated being description of the plant, habits of growth, yield, relative value as a tannin plant, and methods of cultivation. On irrigated land on the station farm the yield was estimated at 4 to 10 tons of green cañaigre per acre. Cañaigre seed germinated satisfactorily.

Canary seed (*Abs. in Agl. Jour. Cape Colony, 8 (1895), No. 5, pp. 108, 109*).—The article gives directions for the cultivation and harvesting of *Phalaris canariensis* grown for the seed.

Analyses of varieties of corn, V. Vedrödi (*Chem. Ztg., 19 (1895), No. 17, p. 350*).—Analyses of American and Hungarian varieties of corn.

American cotton in Turkestan, C. Jonas (*U. S. Consular Rpt. 1895, Jan., pp. 123–125*).

Flax cultivation in Ireland, J. B. Taney (*U. S. Consular Rpt. 1895, Jan., pp. 51–57*).—This report is largely statistical.

Fertilizer experiments on flax in 1894 (*Mitt. deut. landw. Ges., 1895, No. 3, pp. 21, 22*).

What is common millet? A. A. Crozier (*Agl. Sci., 8 (1894), No. 10–11, pp. 449, 450*).

Experiments with varieties of potatoes, J. Dufour and F. Péneveyre (*Chron. Agr. Cant. Vaud, 8 (1895), No. 7, pp. 163–168*).

Mulching potatoes, F. A. Waugh (*Oklahoma Sta. Bul. 15, p. 32*).—Mulching soon after the plants came up largely increased the total yield and afforded larger potatoes and a higher percentage of merchantable potatoes.

Mangel-wurzels, carrots, turnips, ruta-bagas, and sugar beets, C. F. Curtiss (*Iowa Sta. Bul. 27, pp. 114–119*).—As a root crop for most classes of stock the flat turnip is preferred; but carrots are best suited for horses. General notes on varieties and culture of roots and analyses of sugar beets grown in 1894 are given.

Turnips, cabbage, sweet corn, and potatoes, J. Wilson (*Iowa Sta. Bul. 27, pp. 105–108*).—This article consists of notes on these crops during the dry season of 1893. A yield of turnips at the rate of 24 tons per acre was attributed by the author to the frequent and careful cultivation of the surface soil.

Nebraska and the beet-sugar industry, M. Hollrung (*Nebraska Sta. Bul. 38, pp. 97–126*).—This publication is a translation by H. H. Nicholson of a report made on the above subject and published in the *Zeitschrift des Vereins für die Rübenzucker Industrie des Deutschen Reichs*. Special attention is devoted to the conditions of soil, climate, and labor in Nebraska, and the comparative expense of growing an acre of sugar beets in Nebraska and Germany.

Fertilizer experiments on tobacco, Barth (*Mitt. deut landw. Ges., 1895, No. 2, pp. 13–15*).—The effect of potash on burning quality of tobacco is especially noted.

American tobacco for Italy (*U. S. Consular Rpt. 1895, Mar., pp. 422–425*).

Greek tobacco, its composition and statistics of culture, A. K. Dambergis (*Internat. Kong. angew. Chem. Brüssel; abs. in Chem. Centbl., 1895, I, No. 9, p. 491*).

Subsoiling, S. Kelsey (*Rpt. Kansas Bd. Agr. 1895, Mar. 31, pp. 203–206*).—A record of a favorable experience in Kansas.

The press drill vs. the common grain drill, C. F. Curtiss (*Iowa Sta. Bul. 27, pp. 113, 114*).—Winter wheat sown in October with the press drill yielded more than the same variety planted with the common grain drill. The variety of winter wheat recommended is the Turkish Red.

HORTICULTURE.

Influence of climate on onions from seed, J. Troop (*Indiana Sta. Bul. 53, pp. 118, 119, figs. 2*).—Experiments with 3 plats of onions grown from native and foreign seeds to determine their comparative value. The land used was the surface of an old marsh cleared and cropped a year previous. There were sown seeds of the Prizetaker variety, grown in Italy, and also seed grown in Minnesota. French-grown seed of Giant Rocca was sown as a test to show that any difference in yields in the 2 plats of Prizetaker was not due to soil differences.

The seed was sown in 14 in. drills, April 7, and on September 7 the Italian onions were ripe, while the plants from the Minnesota seed were still green and showing very few bulbs. Later in the season some of the Minnesota onions formed small, soft bulbs of little market value. The estimated yield per acre was as follows: Italian Prizetaker 500 bu., Minnesota Prizetaker 33 bu., French Giant Rocca 518 bu. Some of the Minnesota seed was sown also in that State, where it produced a large crop of fine onions.

The experiment is considered as indicating that failure in onion crops is as frequently due to improper climatic conditions as to poor seed.

Sweet potatoes, culture and uses, J. F. DUGGAR (*U. S. Dept. Agr., Farmers' Bul. 26, pp. 30, figs. 4*).—A popular bulletin containing information upon the propagation, soil, transplanting, cultivation, manuring, harvesting and storing, varieties, fungus diseases, insect enemies, uses, and cost of production of sweet potatoes. Propagation by means of sets is advised, although in some cases larger yields have been produced from cuttings. The preferred method of constructing a plant bed is detailed, the potatoes being placed on a thin layer of sand over a thick basis of fresh, moistened barnyard manure, and covered with wood earth. An illustration is given of an artificially heated propagating bed. Sound, well-formed potatoes of small to medium size are recommended, from 2 to 4 bu. furnishing sufficient sets to plant an acre, about 3 " drawings " being made.

A light, well-drained soil is advised, the sets being transplanted on low ridges by hand or mechanical devices when danger from frost is over and the sprouts are from 3 to 5 in. above the ground. Placing the plants 18 in. to 2 ft. apart in 3½ to 4 ft. rows seems to give the best results. Shallow, clean cultivation, discontinued the latter part of the season, is recommended, and moving the vines after the last cultivation is not considered necessary.

Analyses of sweet potato roots and vines, showing the fertilizing ingredients removed by them from the soil, are given, as also formulas for fertilizers to replace the loss. A fair yield per acre is stated to be 185 bu. (10,000 lbs.), extracting from the ground 23 lbs. of nitrogen, 10 lbs. of phosphoric acid, and 50 lbs. of potash, which can be restored to the soil by 150 lbs. of nitrate of soda, 90 lbs. of acid phosphate, and 370 lbs. of kainit.

It is advised that sweet potatoes be kept at a temperature of 75° F. for a week or two after digging, and throughout the winter the temperature be maintained at 50 to 60° F. The storage room or cellar should be dry, to avoid the induction of decay by moisture condensing on the roots.

As varieties for consumption in the Southern States are recommended Sugar Yam, Yellow Yam, and Barbadoes; in the Northern States, Big Stem Jersey and Nansemond; as food for live stock, Providence, Shanghai, Hayman, Red Bermuda, and Southern Queen, these being the most productive.

The diseases treated of are the black rot (*Ceratocystis fimbriata*), soil rot (*Acrocystis batatas*), soft rot (*Rhizopus nigricans*), dry rot (*Phoma batatæ*), white rot, sweet-potato scurf (*Monilochætes infuscans*), stem rot, leaf blight (*Phyllosticta bataticola*), and white leaf scab (*Albugo ipomϾ-panduranæ*). Destroying infected roots and giving a rotation of crops is advised in general, and for the soft rot dusting the stored potatoes with fostite. Brief mention is made of cutworms, flea beetles, tortoise beetles, sweet-potato sawflies, the sweet-potato root beetle (*Cylas formicarius*), and sweet-potato hawk moth. Spraying with Paris green is recommended for all but the root beetle, for which pulling up and burning all affected roots and vines is given as the only remedy.

Drying and canning sweet potatoes are discussed, as also the value of the crop as a food for stock, for which purpose its more extensive use is urged. The average composition of several varieties of sweet potatoes is tabulated, and the relative food value of sweet potatoes and corn compared, by which it is seen that 3 lbs. of sweet potatoes contain nearly as much dry matter and quite as much carbonaceous material as 1 lb. of corn, but less than half as much protein. The cost of growing and harvesting an acre of sweet potatoes, exclusive of rent and fertilizers, is estimated to average about $20.

A summary is appended, embodying the main points of the bulletin.

Sweet potatoes, H. N. STARNES (*Georgia Sta. Bul. 25, pp. 127–161*).—In the abstract of this bulletin in a recent number of the Record (6, No. 9, p. 811) an error occurs in the first line of the quoted passage at the top of page 812 which reverses the author's conclusions. The sentence should read "The split-leaf varieties are among the most unproductive." In the preceding sentence of the abstract the word "Clay," used as a synonym for the variety Shanghai, should be "California."

Notes on tomatoes, M. J. HUFFINGTON (*Colorado Sta. Bul. 30, pp. 26–32*).—Descriptive notes and tabulated data on a comparative test of 39 varieties grown at the station in 1894. The plants were started in a forcing house and handled once before planting in the open ground. They were irrigated 4 times during the growing season. As a rule the newer varieties did not prove equal to the older standard kinds. Maule Earliest of All, Vaughan Earliest of All, Atlantic Prize, Perfection, Rosebud, and Ignotum produced the largest yields. For canning are recommended Beauty, Perfection, Long Keeper, Puritan, Ignotum, and Royal Red.

Report of the horticulturist, S. A. BEACH (*New York State Sta. Rpt. 1893, pp. 543–685, pls. 4, fig. 1*).—This report begins with brief remarks on the horticultural work accomplished by the station during the year in testing varieties, originating new fruits, giving addresses before farmers' clubs and institutes throughout the State, and displaying exhibits at the World's Fair at Chicago and at the State and local fairs.

Vegetables grown for exhibition (pp. 545–598).—A reprint of Bulletin 69 of the station (E. S. R., 6, p. 53).

Variety tests of apples (pp. 599–616).—Descriptive notes on 13 varieties of apples, chiefly of Russian origin, with a table showing the yield of 83 varieties of apples and 14 of crab apples. In addition are given lists of 126 varieties of pears, 7 of quinces, 143 of plums, 86 of peaches, 38 of cherries, 37 of currants, and 212 of gooseberries growing at the station.

Variety tests of grapes (pp. 617–626).—Comparative notes on 42 varieties, the species from which each is believed to have been derived being designated. A list of 210 varieties growing in the station vineyard is appended.

Variety tests of blackberries, dewberries, and raspberries (pp. 626–655).—A reprint of Bulletin 63 of the station (E. S. R., 5, p. 786).

Some experiences in testing strawberries (pp. 656–676).—A reprint from Bulletin 64 of the station (E. S. R., 5, p. 874), with in addition a list of 128 varieties fruiting at the station in 1893, and descriptive and comparative notes on 34 of them.

Strawberry crosses (pp. 677–685).—A reprint from Bulletin 64 of the station (E. S. R., 5, p. 874).

Garden vegetables, F. A. WAUGH (*Oklahoma Sta. Bul. 15, pp. 17–29, figs. 7*).—Comparative notes and tabulated data on 15 varieties of peas, 26 of muskmelons, 25 of watermelons, 34 of cucumbers, 30 of lettuce, 11 of potatoes, 14 of tomatoes, 10 of onions, 4 of okra and salsify. The following varieties are recommended: *Muskmelons*—Early Nutmeg, Jenny Lind, and Banquet; *lettuce*—Denver Market, Hanson, and Henderson New York; *tomatoes*—Dwarf Champion, Dwarf Aristocrat, Perfection, Matchless, Optimus, and Ignotum; *onions*—Prizetaker; *okra*—White Velvet and Dwarf.

The recent apple failures of western New York, L. H. BAILEY (*New York Cornell Sta. Bul. 84, pp. 34, pls. 4, figs. 6*).

Synopsis.—A discussion of the causes of the small apple crops in late years, with letters from a number of prominent orchardists in regard to experience with spraying trees. For the production of large crops is advised liberal tilling, efficient fertilizing, careful pruning, and judicious spraying.

It is stated that one of the most important reasons for the failure of the apple crop is the usual custom of allowing the orchards to run to sod or else growing cereals among the trees. In this way the soil is impoverished and the fruit trees can make but a scanty growth. It is urged that orchards be well drained and frequently and lightly cultivated during the late spring and early summer, followed by the sparing use of nitrogenous fertilizers. The tillage will serve as a conservator of moisture, and in this way prevent great damage by drought. In orchards which have been long in sod the turf should be broken up in the spring while soft by means of a sharp-toothed harrow, and afterwards plowed shallow. As fertilizers, potash and phosphoric acid are recommended, supplemented by nitrogen furnished by green manure crops, especially crimson clover.

The apple scab fungus, however, is believed to be the most prominent factor in crop failures, and its life history and damage are treated of at length and illustrated by a colored plate. Against the scab spraying with Bordeaux mixture is strongly advised, and results of experiments are given showing the benefit to be derived from this method. From 2 to 4 applications of the fungicide, beginning when the blossoms fall, and preferably applied during rainy weather, when the fungus spreads most seriously, are recommended.

It is believed that injurious insects can generally be held in check by means of spraying with Paris green, which can be advantageously combined with Bordeaux mixture. Letters are published from 5 prominent apple growers in the State who have experimented with spraying their trees with Bordeaux mixture, and who unite in urging the importance of early and thorough spraying. The illustrations are of imperfect or diseased fruit and branches and sprayed and unsprayed orchards.

Russian apples in Indiana, J. TROOP (*Indiana Sta. Bul. 53, pp. 123–125*).—Descriptive and comparative notes on 16 Russian varieties fruiting in the station orchard in 1894. The apples are considered as best suited for cooking purposes, although some of them make fair dessert fruit. The trees were hardy, thrifty, and healthy. None of the varieties have so far proved to be winter apples, all of them ripening in the summer and fall. It is believed that in colder climates, such as the northern parts of the United States, the varieties will do even better.

Grapes, F. A. WAUGH (*Oklahoma Sta. Bul. 14, pp. 14, pl. 1, figs. 6*).—This bulletin contains remarks on the location and exposure of the station vineyard, with an account of the methods of planting, pruning, and training employed. The Munson system of pruning and training is adopted, and is liked on account of the height at which the vines are trained, thus avoiding injury to the ripening grapes by reflected heat from the ground. The horizontal training of the shoots also offers less surface to the wind. The vineyard has not been troubled by injurious insects or diseases, with the exception of a temporary attack by the spotted grape beetle (*Pelidnota punctata*), that yielded promptly to spraying with arsenate of lead. Some of the bunches were bagged, which proceeding it is thought improved their appearance and kept them in better condition after ripening.

About 200 species and varieties are grown in the vineyard, of which 85 were in bearing last year. Brief descriptive and comparative notes are given for 33 black, 22 white, and 16 red varieties, showing also the weight and yield per vine. The following varieties are recommended for planting: *Black*—Janesville, Hartford Prolific, Champion, and Early Victor for early varieties; Herbert, Worden, Wilder, Concord, and Barry for general crop; *white*—Faith, F. B. Hayes, and Moore Diamond; *red*—Perkins, Brilliant, Goethe, and Catawba; *wine grapes*—Herbemont, Herman Jaeger, Cunningham, Elvira, Jaquez, and Catawba.

Some obstacles to successful fruit growing, F. W. CARD (*Nebraska Sta. Bul. 39, pp. 127–139, pl. 1*).

Synopsis.—The chief obstacles in the way of orchards in Nebraska are stated to be borers, mice and rabbits, crown galls, nematode galls, and drought. The results of experiments made to obviate these evils are given and remedies suggested.

The flat-headed borer (*Chrysobothris femorata*) is believed to do more damage than any other of the several species attacking fruit trees in the State, being far more injurious than the round-headed borer causing damage in the East. The life history is briefly noted. Experiments were made by applying various substances to the trunks of trees in early summer to prevent the beetles from laying their eggs. They were as follows: Soapsuds containing a little kerosene; carbolic acid and potash wash; potash, lard, and lime wash; white-lead paint; and copperas and lime whitewash. The best result was obtained by means of the white lead paint, although the washes containing potash are also recommended. The mixtures may be applied by means of an old broom, and one application will last 3 or 4 months.

In the case of damage by gnawing by mice and rabbits a thin coating of grafting wax over the injured portion was found to be more satisfactory than the mixture of soil and cow manure usually applied. Keeping the orchards clean from weeds and rubbish is recommended and rubbing the trunks of the trees with bloody meat or other disagreeable substances in the fall.

Crown galls, producing a rough, knotty growth on the trunks at the surface of the ground, are discussed and illustrated from photographs, but no remedy except that of destroying affected trees is suggested. Nematode root galls, which are sometimes found on trees received from the Southern States, it is believed will not cause much trouble in Nebraska on account of the cold winters killing the worms.

The greatest loss to fruit growers is believed to be due to lack of rain, and the question of preventing damage from drought by means of furnishing sufficient moisture to the soil is discussed. It is believed that frequent shallow cultivation will cause a greater conservation of moisture in the soil than can be supplied by irrigation. The opinions of prominent orchardists in the State are quite in support of this view. The planting of wind-breaks by the side of orchards is urged to prevent evaporation by winds. To test the value of different methods of cultivation the station orchard was divided up into plats, one of which was pastured, another mowed, a third harrowed every 2 weeks until the first part of August, while on the fourth shallow cultivation was continued until the beginning of October. The foliage made a much more thrifty growth in the cultivated plats, and the yield of fruit was 17 per cent greater than that from the mowed portion and 14 per cent greater than from that pastured. The moisture content of the soil for the first 20 in. was 20.4 per cent in that part of the orchard cultivated the entire season, against only 14 per cent in the mowed portion. As a result of the experiments frequent shallow cultivation to provide a mulch layer of loose, mellow soil is urged.

Protecting fruit from birds, J. TROOP (*Indiana Sta. Bul. 53, pp. 125, 126, pl. 1*).—In order to protect cherries from destruction by birds during the period of ripening, several trees of Russian varieties were covered with bird netting when the fruit began to ripen. The experiment was found to be successful, completely protecting the fruit, while other trees left open and uncovered were entirely stripped of their fruit. Two 6-year-old trees of Bessarabian cherries bore one half bushel each of fine fruit, while an unprotected tree of the same variety and age lost every cherry upon it. The advisability of thus protecting ripening cherries is believed to be thoroughly established. The expense of netting is small, 4 cts. per square yard, and soon balanced by the increased crops obtained. About 75 sq. yd. of netting were used on trees 10 ft. high.

Relation of blossoms to fruit, J. L. BUDD (*Trans. Iowa Hort. Soc. 1893, pp. 444–447*).—This paper states that flowers possessing slight staminate development produce better fruit than those more perfect. Recently top-worked apple trees produce earlier and hardier blossoms than do other trees, owing to the fact that the constriction at the point of union between graft and stock assists in the greater storage of starch in the twigs, thus furnishing more nutrition. Ringing trees also increases the productiveness and quality of the fruit, and enables the blossoms to withstand a lower temperature, for a similar reason. Drift soils on lower levels were found not to nourish the blossoming branches sufficiently to produce as satisfactory crops as were grown on higher bluff and loess soils. Manuring and irrigating unfruitful trees was found to induce a fair crop of fruit. Culture during the early summer and shading the soil during the hot months by a growth of buckwheat or a mulch of straw or coarse manure improved the general condition of the trees and increased the crops. Varieties produced by crossing native apples on Russian varieties were found to have the hardiness of the Russian parent, as well as quality of fruit approaching that of the native parent.

Best ferns for the North and Northwest, G. W. CARVER (*Iowa Sta. Bul. 27, pp. 150–153*).—This comprises some notes on various ornamental ferns for decorative purposes, several species of maidenhair ferns (*Adiantum* spp.), *Pteris*, *Onychium japonicum*, words ferns (*Nephrolepis*), *Cheilanthes tomentosa*, and *Selaginella* being recommended. Directions are given for propagating and growing ferns, the principal methods of propagation being given as dividing large plants, growing from buds, and growing from spores. Planting the ferns in a mixture of leaf mold, sand, and peat is advised, the pots being frequently watered and liquid manure occasionally applied, a repotting with fresh earth being given from time to time.

What is a cantaloupe? F. A. WAUGH (*Garden and Forest, 8 (1895), No. 376, pp. 183, 184*).—A discussion of the vagueness of the name, which in the South is applied to small, globular, netted, green-fleshed muskmelons, and in the North to larger, ovoid, smoother, yellow-fleshed fruit. The writer believes that the term should be limited to hard, rough-skinned, deeply grooved melons.

Some results obtained in crossing cucurbits, L. H. PAMMEL (*Trans. Iowa Hort. Soc. 1893, pp. 320–322*).—Brief notes on experiments in crossing plants of this kind, different species being found not to hybridize. No immediate results were found to follow crossing.

About mushrooms, the study of esculent and poisonous species, J. A. PALMER, Jr. (*Boston: Lee & Shepard, pp. 100*).

Top grafting the apple, C. G. PATTON (*Trans. Iowa Hort. Soc. 1893, pp. 203–210*).—A report on the answers to a circular letter on the subject sent out to numerous fruit growers in Iowa and adjoining States in regard to the influence of stock and scion. It is stated that the seedlings of a species make the best stocks for the different varieties of that species. The Transcendent crab is recommended for some varieties, especially Russian. It is advised that top grafting be done low when the stock is from 3 to 7 years old.

Dried apples in Germany, W. H. ROBERTSON (*U. S. Consular Rpt. 1895, Jan., pp. 89–92*).—A brief mention of official measures being taken in Germany to prevent the sale of American dried apples on the ground of their containing zinc. The writer urges that American producers of dried apples use wooden trays for drying, thus avoiding any objections on the point of zinc adulteration. It is believed, however, that the unwholesomeness of the fruit has been exaggerated.

New seedling plums, H. A. TERRY (*Trans. Iowa Hort. Soc. 1893, pp. 275, 276*).—Descriptive notes on 19 varieties, chiefly originating in Iowa.

Stone fruits in 1893, J. L. BUDD (*Trans. Iowa Hort. Soc. 1893, pp. 136–141*).—Some notes on experiments in propagating plums and cherries, with remarks on some other stone fruits. The sand cherry is recommended as a promising stock.

Top grafting, N. E. HANSEN (*Trans. Iowa Hort. Soc. 1893, pp. 362–364, fig. 1*).—Some popular directions on the subject.

New varieties of small fruit, R. D. MCGEEHON (*Trans. Iowa Hort. Soc. 1893, pp. 43–45*).—Brief descriptive notes on 11 recent varieties of strawberries, 5 of raspberries, and 1 of blackberries.

Strawberry culture, R. D. MCGEEHON (*Trans. Iowa Hort. Soc. 1893, pp. 456–459*).—Notes on successful methods, the details of cultivation being given.

Small fruits, C. ROOT (*Trans. Iowa Hort. Soc. 1893, pp. 68–72*).—A brief article on the cultivation, manuring, varieties, winter protection, and spraying of small fruits, particularly strawberries.

The Munson grape trellis, F. A. WAUGH (*Garden and Forest, 8 (1895), p. 186*).

Fruit culture, W. A. LUCE (*Maine Bd. Agr. Rpt. 1893–'94, pp. 188–191*).—A general popular paper on the culture of small fruits, strawberries being mentioned in particular.

Varieties and localities, C. L. WATROUS (*Trans. Iowa Hort. Soc. 1893, pp. 311–316*).—A popular discussion of the variation in the same variety when grown in different climates and latitudes.

The blossoms of the orchard fruits, N. E. HANSEN (*Trans. Iowa Hort. Soc. 1893, pp. 154–157*).—Notes on investigations to determine the reasons for the nonfertility of fruit blossoms. Plums, pears, and apples were experimented with, and numerous varieties were found to be self-sterile owing to peculiar development of the sexual elements.

Definite annual growth and its relations to hardiness, L. H. PAMMEL (*Trans. Iowa Hort. Soc. 1893, pp. 104–113, pl. 1*).—A discussion of the subject from the standpoint of morphological botany, with notes on a number of varieties of apple trees.

The improvement of our native fruits, B. A. MATTHEWS (*Trans. Iowa Hort. Soc. 1893, pp. 102, 103*).—Brief notes on some improved Iowa wild fruits, chiefly plums, crab apples, mulberries, juneberries, and gooseberries.

The relation of soil and climate to Iowa horticulture, D. A. KENT (*Trans. Iowa Hort. Soc. 1893, pp. 73–76*).—A popular paper giving an analysis of a sample of Iowa black loam and stating that the fertility of the prairie is due to the fact that the soluble elements in the soil are protected by freezing during the period of the greatest precipitation, when they might otherwise be dissolved and carried off by the rains.

Horticulture from a climatic standpoint, J. R. SAGE (*Trans. Iowa Hort. Soc. 1893, pp. 143–147*).—The author urges the careful study of the yearly temperature in determining the varieties to be grown, and the importance of furnishing the proper supply of moisture.

Horticultural lessons from the Columbian Exposition (*Trans. Iowa Hort. Soc. 1893, pp. 96–102*).—General article on the subject, with special reference to the Iowa fruit display.

The farmer's fruit and vegetable garden, W. S. FULTZ (*Trans. Iowa Hort. Soc. 1893, pp. 177–180*).—A general paper giving popular instructions and recommendations.

Fruit farming in Luxemburg, G. H. MURPHY (*U. S. Consular Rpt. 1895, Jan., pp. 75–80*).

The commercial preservation of fruits, J. L. BUDD (*Trans. Iowa Hort. Soc. 1893, pp. 270–272*).—A discussion of the methods of preserving fruit by means of cold storage, drying, and canning.

Exhibit of fruits and vegetables at the World's Fair, P. COLLIER (*New York State Sta. Rpt. 1893, pp. 173–176*).—A brief mention of the display sent by the station to Chicago, comprising 40 varieties of strawberries, 25 of currants, 167 of gooseberries, several of stone fruits, 17 of pears, 97 of apples, 154 of grapes, 433 of various vegetables, and specimens of sprayed and unsprayed branches and fruit. A list is given of the awards granted the station exhibits by the World's Fair Commissioners, and the exhibit made by the station at the State fair is summarized.

Laws of floral colors, E. M. BUDD (*Trans. Iowa Hort. Soc. 1893, pp. 53–56, fig. 1*).—A technical discussion of the subject, explaining the presence of special colors on chemical and physical grounds.

Hollies and their culture, J. MEHAN (*Cult. and Country Gent., 1895, Apr. 18, p. 308*).

Rose hybrids, J. L. BUDD (*Trans. Iowa Hort. Soc. 1893, pp. 359–361*).—Some brief notes on crossing roses, the hybrid seedlings being more vigorous than pure seedlings and blooming earlier.

Grafting the cacti, G. W. CARVER (*Trans. Iowa Hort. Soc. 1893, pp. 257–259*).—Notes on experiments in this line, cleft grafting and tongue grafting being most successful.

FORESTRY.

Conifers in the West, C. A. KEFFER (*Garden and Forest, 8 (1895), p. 182*).—Notes on red cedar, European larch, *Pinus resinosa*, arbor vitæ, spruces, and fir trees.

Rocky Mountain conifers, M. E. HINKLEY (*Trans. Iowa Hort. Soc. 1893, pp. 94, 95*).—A brief article treating of the manner in which some of the western evergreen trees were brought into public notice.

Four native trees in the Northwest, L. C. CORBETT (*Garden and Forest, 8 (1895), p. 173*).—Notes are given on the cottonwood, box elder, green ash, and white elm.

The European larch as a timber tree, N. A. REEVES (*Trans. Iowa Hort. Soc. 1893, pp. 176, 177*).—A brief note on a large planting of larches made some 20 years before, the trees being favorably regarded for their rapid growth, beauty, and timber value.

Evergreens for shelter belts, C. F. GARDNER (*Trans. Iowa Hort. Soc. 1893, pp. 90–92*).—The author advises the planting of evergreen trees as protection against winds, Norway spruces being especially recommended for the purpose.

Notes on rubber-yielding trees (*Bul. Bot. Dept. Jamaica, n. s., 2 (1895), No. 3, pp. 31–38*).

DISEASES OF PLANTS.

Field experiments with fungicides, B. D. HALSTED (*New Jersey Stas. Bul. 108, pp. 32, dgms. 2*).

Synopsis.—A report is given of field experiments with fungicides for the control of the diseases of turnips, cabbage, tomatoes, potatoes, and beans.

A preliminary report of this paper was read before the section on horticulture and botany of the Association of American Agricultural Colleges and Experiment Stations at its meeting in November, 1894, a brief abstract being given in E. S. R., 6, p. 267.

The experiments were conducted on an acre, equal portions of which were devoted to each crop. Diagrams are given of the area used in the experiments, showing the manner in which it was divided. Each of the one fifth acre portions, called series, was divided into 4 plats, and these in turn were divided into 6 equal belts. In this way adjacent portions of essentially the same character could be used for check and test experiments.

Experiments with turnips (pp. 6–14).—The soil selected was badly infected with the club root fungus (*Plasmodiophora brassicæ*), a badly affected crop of turnips having grown upon it the year before. Two crops of turnips were grown and before the seed was sown the soil received treatments of air-slacked lime, gas lime, kainit, and wood ashes in different amounts, and on the cultural belt accompanying every plat were used corrosive sublimate, Bordeaux mixture, and ammoniacal copper carbonate. In the treatment of the first crop the applications to the belts were as follows: Air-slacked lime 150, 75, and 37½ bu. per acre; gas lime 75, 37½, and 18¾ bu. per acre; kainit 1,920, 960, and 480 lbs. per acre; and wood ashes 150, 75, and 37½ bu. per acre. The fungicides used were applied as follows: Corrosive sublimate, 960 gal. of a $\frac{1}{2000}$ per cent solution per acre; Bordeaux mixture, one half strength, 960 gal. per acre, and one half strength ammoniacal copper carbonate, 960 gal. per acre. In belt 4 the plants were sprayed once in 20 days with Bordeaux mixture. Where the full strength of lime was used much of the seed failed to germinate. The gas lime seemed to retard growth to a considerable degree, and kainit, in all strengths used, proved detrimental to germination. Wood ashes did not affect germination, and the plants growing in the belts receiving it grew more rapidly than the others. Five weeks after the seed was sown the presence of club root was shown to some degree and it spread rapidly from that time on.

The crop was harvested July 24 and it was found that the treatments gave almost wholly negative results in preventing club root. August 10 a second seeding was made, the soil having received treatment 4 days before, the proportions of the fungicides being somewhat modified. From the results obtained the author concludes as follows:

> "Air-slacked stone lime gave sufficient evidence of its usefulness as a preventive of club root of turnips to warrant its being recommended for this purpose. When so employed it is advised that it be used at the rate of not less than 75 bu. per acre and applied at least 3 months previous to the time of planting.
>
> "Gas lime, kainit, and ashes all failed to prevent the malady. Gas lime and kainit are both injurious to the crop.
>
> "A half-strength solution of corrosive sublimate applied to the soil at the rate of 4,320 gal. per acre was not harmful to the plants and gave evidence of having materially diminished the amount of clubbing. Equal quantities of half-strength solution of Bordeaux mixture and ammoniacal copper carbonate proved of no value as club root fungicides and were decidedly injurious to the plants. Half-strength Bordeaux mixture applied to the foliage once in 20 days did not prevent turnip-leaf blight."

Experiments with cabbage (pp. 14–18).—The experiments with cabbage were conducted under the same conditions as the experiments above described for the turnips. The conclusions of the author are as follows:

> "Air-slacked stone lime is a preventive of the club root of cabbage. The best results were obtained from the smallest application—that is, at the rate of 75 bu. per acre.
>
> "Gas lime, kainit, and wood ashes are all equally ineffective as club root fungicides.
>
> "A half-strength solution of corrosive sublimate at the rate of 2,160 gal. per acre can not be recommended, for although an apparent preventive of club root, the solution is destructive to the plants. A weaker solution might prove just as effective as a fungicide without interfering with growth.
>
> "Neither half-strength Bordeaux mixture nor ammoniacal copper carbonate when used at the above rate diminished the amount of clubbing and both were very injurious to the plants."

Experiments with tomatoes (pp. 18–20).—In these experiments the object was to test the effect of various strengths and number of applications of Bordeaux mixture and ammoniacal copper carbonate required for the prevention of the various diseases affecting the tomato. Three strengths of solutions were used, and in testing the number of applications required from 2 to 8 sprayings were given the plants. Late in the season several diseases were noticed on sprayed and check plants, but not in any great abundance. The diseases were so poorly shown on the check plants that the results have little if any practical bearing. The experience of the author in staking tomato plants so as to raise the stem and branches clear of the ground led him to conclude that such treatment was not advisable.

Experiments with potatoes (pp. 20–24).—The fourth series of experiments was with potatoes, an effort being made to prevent scab by the use of different strengths and methods of application of corrosive sublimate and Bordeaux mixture. In the cultural belts the plants were sprayed for the prevention of leaf diseases, but so little disease was present on the checks as to render these experiments of little value.

At harvest the tubers were weighed and the weight of sound and scabbed potatoes ascertained. The author's conclusions as to the value of the treatment as shown by his experiments are as follows:

> "Potatoes soaked in, and sprayed in the open rows with, quarter-strength corrosive sublimate gave a larger yield and a lower per cent of scab than did either of the belts treated with half and full strength solutions of the same compound. Similar results followed the treatment of seed potatoes with quarter-strength Bordeaux mixture.
>
> "Although there was but little apparent difference in value between corrosive sublimate and Bordeaux mixture, the former is considered preferable on account of its being more easily prepared, and as it is of a uniform strength throughout admits of a much greater quantity of potatoes being treated at one time than does the Bordeaux mixture, which soon settles unless stirred.
>
> "The cutting of the 'seed,' before soaking in Bordeaux mixture, showed very emphatically the importance of applying the fungicide to the uncut potatoes and preparing them afterwards for planting."

Experiments with beans (pp. 24–30).—Two crops of Golden Wax beans were grown in the last series, the object being to test different strengths and times of application of fungicides. Based on the results of his experiments with the beans, the author concludes that—

> "Soaking bean seed in either full, half, or quarter-strength Bordeaux mixture does not prevent anthracnose.
>
> "Spraying the vines with full-strength Bordeaux mixture or full-strength ammoniacal copper carbonate every 10 days is a partial preventive of anthracnose and bacterial blight, and when applied to the seedlings within a few days after their first appearance and repeated at intervals of 5 days is an almost complete preventive.
>
> "Half-strength Bordeaux mixture and half-strength ammoniacal copper carbonate gave equally good results as leaf fungicides, and are preferable to the full or quarter-strength solutions of either of the above compounds. As fungicides they are as effective as the stronger solutions, and, unlike them, do not injure the vines. The quarter-strength solutions are less effective as fungicides."

The formulas for the fungicides used and methods for their preparation and application are given in detail.

Notes on finger and toe (club root) of cabbage and allied plants, G. MASSEE (*Proc. Roy. Soc., 57 (1895), No. 344, pp. 330–332*).—The author briefly refers to the observations of several authors on the disease of crucifers caused by *Plasmodiophora brassicæ* and gives an account of some experiments conducted by himself. He found (1) that in addition to cultivated plants, several weeds belonging to the order *Cruciferæ* are attacked by *Plasmodiophora*. Hence the necessity of preventing the growth of such weeds in fields, etc. (2) That the germs of disease remain in the soil and retain their vitality for at least 2 years. (3) The development of *Plasmodiophora* is favored by the presence of acids and checked by the presence of alkalies, in this agreeing with fungi rather than bacteria. (4) For the purpose of sterilizing infected soil, experiments prove that either a dressing of lime or a manure containing potash salts is effective, the last being most valuable, as it not only destroys the germs in the soil but arrests the disease in seedling plants and at the same time supplies one of the ingredients necessary for the healthy growth of turnips, etc.

Treatment of melon diseases, F. A. WAUGH (*Oklahoma Sta. Bul. 15, pp. 30–32, fig. 1*).—Brief notes are given of anthracnose of watermelon, due to *Colletotrichum lindemuthianum*. In 1894 experiments were conducted for its repression. Seeds were soaked in Bordeaux mixture and copper carbonate solution before planting, and in a second trial the plants were sprayed at different intervals throughout the growing season. The results were wholly negative and the experiments are to be repeated.

Potato blight and potato scab, F. W. RANE (*West Virginia Sta. Bul. 38, pp. 39–46, figs. 5*).—A popular bulletin in which potato blight due to *Macrosporium solani* and potato scab are figured and described. The use of Bordeaux mixture is advised as preventive treatment for the blight and soaking seed potatoes in corrosive sublimate for the prevention of the scab. Notes are given on spraying apparatus and also list of firms making such machines.

The author tested the effect of barnyard manure and lime on the production of scab. The most scab was found in the plats receiving the manure, the plat receiving lime gave the next amount, lime and manure still less, and no treatment gave the least amount of scab. All the seed was untreated in this experiment.

Potato scab, J. TROOP (*Indiana Sta. Bul. 53, pp. 120–122, figs. 2*).—The author conducted some experiments to ascertain (1) whether or not the disease is developed more rapidly in muck soil than in sandy loam; (2) whether a single crop of scabbed potatoes will render the soil unfit for a future crop, and (3) the effect of treatment on the yield. The tubers were soaked in a solution of corrosive sublimate, 2 oz. to 16 gal. water, for 1, 1.5, and 3 hours. In every case the longer the seeds were soaked the less was the amount of scab. In the case of the muck soil there was a greater amount of scab on both treated and untreated plats than on the upland soil. In the muck the untreated plats gave 60 to 65 per cent scabbed tubers, as compared with 3.5 to 5.75 per cent for the treated plats. On the upland the amount of scab was reduced to 2 per cent by the treatment. The germs from an infected crop of the previous year materially increased the amount of scab at harvest. Owing to a frost killing some plants the third inquiry was abandoned, as the results were too unreliable for comparison.

Potato scab and its prevention (*Iowa Sta. Bul. 27, pp. 120–129, figs. 3*).—Compiled notes are given concerning the cause of potato scab, and suggestions are given for its prevention. Experiments were conducted to test the relative value of corrosive sublimate, ammoniacal copper carbonate, potassium sulphid, Bordeaux mixture, ferrous sulphate, soda hyposulphite, and a sulphur mixture for the prevention of scab. Owing to the season the results obtained were such that no definite conclusions could be drawn, but the corrosive sublimate was thought to have given the best results, when total yield and per cent of scab are considered.

Ruta-baga rot, L. H. PAMMEL (*Iowa Sta. Bul. 27, pp. 130–134, pl. 1*).—An abstract of this article was presented to the section on botany and horticulture of the Association of American Agricultural Colleges and Experiment Stations at its meeting in November, 1894 (E. S. R., 6, p. 268).

The disease was first noticed in 1892 and in 1893 was so severe as to destroy in one case more than 50 per cent of the crop. When present this rot may be recognized by its peculiar odor. Usually the crown of the root is the portion first affected, but occasionally the bases of the leaves are first to show the disease, or it may appear on the side of the root. The leaves of all plants affected were spotted, but the author has not attempted to study the relationship between the leaf spotting and the rotting of the roots. The fibrovascular bundles of diseased roots become black and the adjacent parenchyma is of a watery appearance. In roots badly affected the cortex easily separates from the fleshy portion. Sometimes the stems and roots become hollow, containing an ill-smelling fluid. In this fluid numerous bacteria were found, some of which were isolated, and from inoculation experiments one was found that the author considers the cause of the disease. He has given to it the name *Bacillus campestris* n. sp., characterized as follows:

> "Bacillus varying somewhat in length from 1.87 μ, 2.25 μ, to 3 μ, width uniform 0.37 μ. Rods rounded at ends, occurring singly or in chains of two or three, staining uniform and readily with fuchsin and gentian violet; in old cultures it stains with difficulty. In hanging drops the bacillus exhibits a lively motion. The organism has considerable vitality, cultures 4 months old growing readily when transferred. Spores not observed."

In the various cultures the bacteria produces a characteristic yellowish growth.

The disease affects ruta-bagas and yellow turnips. No specific suggestions are given for its prevention.

Observations on Plowrightia morbosa, S. A. BEACH (*New York State Sta. Rpt. 1893, pp. 686–688*).—During 1893 a plum nursery was examined at the request of its owner for black knot. The young trees were budded in 1891 and in 1893 no wood was left above the union but 2-year-old growth. One side of a block of the young trees was bordered by a row of bearing plum trees that were badly affected by the black knot, some of the branches of the diseased trees overhanging the nursery stock. In 1892, after the leaves had fallen, all knots were cut from the old trees. On June 28, 1893, nearly every young tree immediately under the old ones was badly affected, and a careful inspection showed some evidence of the disease in other rows. The conclusion of the author is that the infection undoubtedly came from the older trees-there being no other adequate source of infection, and from the fact that the young trees under the drip of the older ones were the ones worst affected.

The author claims that the infection of the young trees could only have been through the conidia formed during 1892, as the old knots had been removed in the fall of 1892 before any ascospores were formed. This point is of economic interest in showing that a serious attack of the disease may follow from the conidia formed during the summer months as well as through the ascospores formed during the winter and early spring.

Spraying orchards and potato fields, L. R. JONES (*Vermont Sta. Bul. 44, pp. 81–102, figs. 14*).

Synopsis.—A report is given on the relation of weather of 1894 to plant diseases, apple and pear scab and the means for its repression, results of spraying potatoes in 1894, observations upon the date of planting potatoes, and on the prevention of potato scab.

Relation of weather of 1894 to plant diseases (p. 82).—Owing to the remarkably dry season of 1894 there were no serious attacks of parasitic fungi, some plants escaping almost entirely. While plant diseases were not troublesome the dry weather brought conditions resulting in unusual insect activity. The results shown on the sprayed plats, while not as marked as in previous years, still gave enough difference over the unsprayed crop as to indicate that spraying will be profitable.

Apple and pear scab (pp. 82–93).—Illustrated notes are given on the cause of apple and pear scab and the results of a series of experiments conducted for its repression are reported. Three varieties of apple trees and 1 of pears were sprayed with Bordeaux mixture, different lots of the trees receiving 4, 5, 6, and 7 applications. The results given showed that for that year 4 sprayings were sufficient. The gains as shown by the character of the fruit produced were 23, 24, and 27 per cent for the apples and 117 per cent for the pear trees. Directions are given for the preparation and application of the fungicide.

Results of spraying potatoes in 1894 (pp. 93–98).—Applications of Bordeaux mixture were given to the potato plants, but owing to the dry season but little disease was noticed. There were, however, severe ravages of grasshoppers and flea beetles. The use of the usual insecticides seemed to have little effect, but it was noticed that those plants which had been sprayed with Bordeaux mixture escaped serious injury. From the treated plats an increased yield over the check plats was secured, due no doubt to the combined fungicidal and insecticidal effect of the Bordeaux mixture. The author thinks he is warranted in recommending the use of Bordeaux mixture on either early or late varieties of potatoes during either a wet or dry season. Paris green may be added to the mixture for the destruction of the Colorado beetle.

Observations on the date of planting potatoes (pp. 98–100).—In the Annual Report of the station for 1893, p. 55 (E. S. R., 6, p. 908), the author called attention to the greater liability to disease of late planted potatoes. Ordinarily the early crop of potatoes is less productive than the later, owing to the fact of the tubers usually maturing in July, the driest month of the year, but in 1894 the season was so peculiar that the early crop was the most productive. It is believed that for the average season late planting is the most profitable, in spite of the fact that the plants must be sprayed to protect them against the late blight.

Potato scab (pp. 100-102).—Brief notes are given on the cause of potato scab and recommendations given for its prevention. The author advises the use of clean seed, planting in clean soil, and the use of clean fertilizers. Where the seed potatoes are not known to be free from the scab it is suggested that they be soaked in a solution of corrosive sublimate before planting. After such a treatment the yield of merchantable potatoes in one of the author's experiments increased more than 50 per cent in 1894.

New species of parasitic fungi, S. M. TRACY and F. S. EARLE (*Torrey Bul., 22 (1895), No. 4, pp. 174-179*).—Descriptions are given of the following new species of parasitic fungi: *Puccinia notabilis* on *Pluchea borealis* (?), *P. paspali* on *Paspalum virgatum*, *Ustilago crus-galli* on *Panicum crus-galli*, *U. tonglinensis* on *Ischæmum ciliare* from India, *U. ornata* on *Leptochloa mucronata*, *U. pertusa* on *Setaria macrochæta* from Queensland, *U. pustulata* on *Panicum proliferum*, *Dimerosporium magnoliæ* on *Magnolia virginiana*, *Asteridium illicii* on *Illicium floridanum*, *Sphærella andromedæ* on *Pieris nitida*, *Lembrosia angustiformis* on *Ilex coriacea*, *L. prinoides* on the same, *L. illiciicola* on *Illicium floridanum*, *Vermicularia stachydis* on *Stachys affinis*, *Diplodia minuta* on *Tecoma radicans*, *D. sassafras* on *Sassafras officinale*, *Hendersonia taphrinicola* on blisters of *Taphrina* on *Quercus virginiana*, *Pestalozzia cliftoniæ* on *Cliftonia ligustrina*, *P. breviaristata* on *Tecoma radicans*, *Scolecotrichum punctulatum* on *Iris pabularia*, *Cercospora flexuosa* on *Diospyros virginiana*, *C. graminicola* on *Phleum pratense*, *C. hibisci* on *Hibiscus esculentus*, *C. mississippiensis* on *Smilax glauca* and *S. rotundifolia*, and *Tetraploa divergens* on *Panicum agrostidiforme*.

Grain smuts and potato scab, A. NELSON (*Wyoming Sta. Bul. 21, pp. 24, figs. 4*).—Popular illustrated notes are given on the cause and distribution of grain smuts and potato scab. Directions for the hot water and copper sulphate treatments are given and the former recommended as the more efficient treatment for the prevention of grain smut. For the potato scab soaking the seed tubers in corrosive sublimate is advised and the precautions to be observed in such treatment are mentioned.

Root rot of beets, HILTNER (*Sächs. landw. Ztschr.; abs. in Landw. Centbl. Posen, 23 (1895), No. 14, pp. 79, 80*).

The drooping disease of tomatoes, G. ABBEY (*Jour. Hort., n. s., 1895, No. 774, p. 360*).—A disease due to a slime fungus, *Plasmodiophora tomati*, is described. The treatment is the same as for club root of cabbage.

Diseases of the cherry, L. H. PAMMEL (*Trans. Iowa Hort. Soc. 1893, pp. 248-253*).—An account of the spot disease (*Cylindrosporium padi*), cherry and plum scab (*Cladosporium carpophilum*), cherry powdery mildew (*Podosphæra oxacanthæ*), and black knot (*Plowrightia morbosa*), the descriptions being in sufficient detail to be of value to working horticulturists.

Brunnisure of the vine, U. BRIZI (*Staz. Sper. Agr. Ital., 28 (1895), No. 2, pp. 112-128, pl. 1*).

A root rot of cyclamen, P. SORAUER (*Ztschr. Pflanzenkrank., 6 (1895), No. 1, p. 18*).—A disease caused by the mycellium of a fungus, probably *Thielavia basicola*, in the soil.

A disease of the violet (*U. S. Consular Rpt. 1895, Jan., p. 130*).

Parasitism of Agaricus melleus on oak roots, HARTIG (*Bot. Centbl., 52 (1895), No. 2, p. 48*).

Plant diseases, M. C. COOKE (*Gard. Chron., 17 (1895), pp. 496, 497*).—A lecture on plant diseases, their cause and means of repression.

The occurrence of Peronospora parasitica as influenced by the nature and development of the host plant, P. MAGNUS (*Ber. deut. bot. Ges., 12 (1894), Generalversammlungs number, 1895, Feb. 12, pp. 39–44, pl. 1*).

On the polymorphism of the genus Sporotrichum, E. BOULANGER (*Rev. gén. Bot., 7 (1895), No. 75, pp. 97–102; 76, pp. 166–170*).

Naphtholate of soda as a fungicide (*Prog. Agr. et Vit., 12 (1895), No. 16, pp. 422, 423*).

On combating grain rusts, W. SCHEUTLE (*Fühling's landw. Ztg., 44 (1895), No. 4, p. 131*).

On the prevention of injuries to grain, STEGLICH (*Landw. Jahrg., 3 (1895), No. 8, p. 44*).

When to spray (*Amer. Gard., 16 (1895), No. 38, pp. 180, 181, figs. 5*).—Extracts are given of New York State Station Bulletin 84.

Preventing leaf blight of plum and cherry nursery stock, S. A. BEACH (*New York State Sta. Rpt. 1893, pp. 688–693, pls. 2*).—A reprint of Bulletin 72 of the station (E. S. R., 6, p. 302).

Experiments in preventing pear scab, S. A. BEACH (*New York State Sta. Rpt. 1893, pp. 694–717, pls. 3*).—A reprint of Bulletin 67 of the station (E. S. R., 5, p. 986).

ENTOMOLOGY.

Insect Life (*U. S. Dept. Agr., Division of Entomology, Insect Life, vol. VII, No. 4, pp. 281–360, figs. 7*).—*Special notes* (pp. 281, 282).—These comprise remarks on the new cotton-boll weevil, Florida insects and the December freeze, and Bulletin 33, Division of Entomology.

Further notes on the San José scale, L. O. Howard (pp. 283–295).—A general résumé of the information on this pest, comprising notes on its life history, distribution, original home, future, and remedies. It is stated that the insect does not lay eggs, but is viviparous, the females continuing to give birth to living young for several weeks. It is believed that there are 5 annual generations in the latitude of Washington. *Aphelinus fuscipennis* is the only parasite which has so far been found in the East. The belief is held that the origin of the scale is in Australia. Spraying with a strong solution of whale-oil soap or a very strong resin wash is the only means that has proved effectual as a remedy, but the expense involved will probably interfere with its general adoption.

Report on the Mexican cotton-boll weevil in Texas, C. H. T. Townsend (pp. 295–309).—A report on the life history of *Anthonomus grandis* and the injury inflicted by it on the cotton crop in Texas. Both the larvæ and adults were found to feed on the cotton bolls, the eggs usually being deposited in the unopened flower buds. The weevil infested Texas from the adjacent State of Coahuila, Mexico, and now occupies the extreme southern portion of Texas, keeping near to the coast and extending from Brownsville to San Antonio, or about one sixth of the cotton producing region of the State. It is estimated that a loss of 90 per cent of the cotton crop in the infested region was caused by the weevil in 1894. Burning over all infested fields during the winter, followed by flooding them for a week or two, and rotation of crops for at least 2 years is recommended. It is thought that arsenical spraying when the bolls begin to form may be advantageous. It is urged that cotton raising be abandoned along the southern Texas border to prevent further importation of the weevil, and that legislation be made providing for quarantine measures.

The cotton or melon plant louse, T. Pergande (pp. 309–315).—Bibliographical notes on *Aphis gossypii*, establishing its identity with the orange, melon, and cucumber aphides. A long and varied list of food plants is given and technical descriptions of the pupæ and adult females.

The cotton worm question in 1894, E. A. Schwarz (pp. 315–320).—Notes on the methods adopted throughout the cotton region for combating the cotton worms, the preferred method at present being dusting the plants with Paris green applied by means of sacks attached to a pole on the back of a horse or mule.

Notes on cotton insects found in Mississippi, W. H. Ashmead (pp. 320–326).—A continuation of previous papers. In this installment the Hemiptera, Lepidoptera, and Diptera are treated.

On the distribution of certain imported beetles, F. H. Chittenden (pp. 326–332).—Notes on 18 species of the beetles attacking stored grains, vegetables, dried fruits, and drugs.

Injurious insects and commerce, L. O. Howard (pp. 332–338).—A general paper on the subject, treating briefly of several more injurious insects, chiefly imported, and urging the importance of attentive and watchful study of economic insects and the passage of quarantine laws.

Is Cyrtoneura cæsia an injurious insect? D. W. Coquillett (pp. 338, 339).—A note on the occurrence of this European insect in squash roots in Colorado, where it is believed the flies were present as scavengers.

Insect fertilizers of an aroid plant, H. G. Hubbard (pp. 340–345).—Illustrated notes on the fertilization of the flowers of *Philodendron* sp. in Montserrat by the beetle *Macrostola lutea*, which burrows through the spathe to deposit its eggs upon the spadix, where the flowers are by this means fertilized with pollen from other plants of the species.

Notes and observations on the twig girdler, C. H. Scheffer (pp. 345–347).—An account of the methods employed by *Oncideres cingulata* in laying its eggs and girdling the twigs.

A Cecidomyid that lives on poison oak, D. W. Coquillett (p. 348).—Technical description of *Cecidomyia rhois*, a new species forming galls on the roots of *Rhus toxicodendron.*

A migration of cockroaches, L. O. Howard (p. 349).—A brief note on the migration of several thousand egg-bearing croton bugs (*Ectobia germanica*) from an old restaurant to other buildings.

The potato-bud weevil, F. H. Chittenden (pp. 350–352).—Brief observations on the life history of *Anthonomus nigrinus*, which deposits its eggs in the buds of horse nettles and potatoes. It is believed to be single brooded.

An ortalid fly injuring growing cereals (pp. 352–354).—Notes on the life history of *Chætopsis ænea*, which burrows in the stem of wheat, oats, corn, and sugar cane to a varying extent.

The gray hair-streak butterfly and its damage to beans (pp. 354, 355).—An illustrated note on *Uranotes melinus*, the larva of which has been discovered feeding upon beans, chiefly Limas. The injury has not been serious.

Among *general notes* and *notes from correspondence* may be mentioned the following: A home-made cover for fumigation with bisulphid of carbon, the imported parasite of the Hessian fly, a remarkable migration of butterflies, are tumblebugs beneficial? Margarodes in the United States, the scale insects of Arizona, larvæ in mincemeat, a lachnosterna damaging wheat in Texas, spread of *Cryptorynchus lapathi*, new food plant for the San José scale, the new plum aspidiotus in Illinois, and the Florida red scale in a northern greenhouse.

A preliminary list of the honey-producing plants of Nebraska, C. E. BESSEY (*Nebraska Sta. Bul. 40, pp. 141–152*).—This consists of a list of 157 species of native and introduced plants, yielding nectar, and in many cases pollen as well. It is not stated that hive bees visit all of the flowers included, and the list is undoubtedly far from complete, but it is valuable as being the most extensive list of this nature yet published.

The chinch bug, O. LUGGER (*Minnesota Sta. Bul. 37, pp. 153–182, figs. 12*).—This is a popular bulletin issued for the information of farmers on account of threatened damage by chinch bugs, and treating rather fully of the appearance and life history of the pest, especially mentioning vulnerable points in its habits and its diseases and insect enemies. Directions are given for identifying the chinch bug, particularly by means of the black spots on the white wing covers, and descriptions and figures of the insects most frequently confused with it. The subject of fungus diseases is treated of at length, their action being described in detail, and directions given for their propagation and application to the bugs.

Clean cultivation is urged as a preventive, and in case of an invasion active measures by means of digging ditches into which the bugs may fall during their migrations and can be destroyed by burning; spraying with kerosene emulsion when only the edge of a field is attacked is also advised, but the most confidence is placed in fungus diseases, especially if the weather be damp.

The fruit bark beetle, Scolytus rugulosus, J. TROOP (*Indiana Sta. Bul. 53, pp. 126–130, figs. 7*).—Illustrated descriptive, life history and remedial notes on this fruit pest that has recently begun attacking fruit orchards in Indiana. Apple, pear, plum, peach, and cherry trees seem to be attacked in preference, although various shade and ornamental trees are also infested. The eggs are laid in September by the female burrowing under the bark of the trunk and larger branches, forming little channels where the larvæ feed and hibernate, emerging as adults in early spring. There is a second brood in the summer. The insect was discovered attacking both healthy and diseased trees.

It was found that spraying the trunks and branches with kerosene emulsion, as well as with a combination of Bordeaux mixture and Paris green, prevented the attacks of the beetle over the portion sprayed. Spraying with either of these remedies is therefore recommended, the application preferably to be made before any marks of attacks by the insects are found on the trees. Where trees are severely infested cutting them down and burning them through the winter is advised.

A plum scale in western New York, M. V. SLINGERLAND (*New York Cornell Sta. Bul. 83, pp. 681–699, pl. 1, figs. 4*).—This contains the results of investigations on a supposedly new species of scale insect belonging to the genus *Lecanium*, which has suddenly developed in alarming prevalence in the plum orchards of the State. Notes are given on the appearance of the pest, its life history, damage, enemies, and the most advantageous remedies. The minute, brown, spindle-shaped young scales that have survived the winter on the branches begin to move about April 1, soon locating themselves permanently, increasing rapidly in size, and becoming adult in about 2 months. The adult females are dark brown and almost hemispherical, resembling small brown split peas adhering to the branches, on which white scars are left on the removal of the scales. The males are smaller, flat, elongate, and whitish. Several hundred eggs are laid by each female in June, hatching in about a month, and the young migrate in August and September to the spots where they hibernate. There is but one annual brood.

The damage done by the scales is chiefly confined to plums, although other trees are attacked when adjacent to infested plum trees. The Japanese varieties of plums are apparently exempt from attack.

The twice-stabbed ladybird (*Chilocorus bivulnerus*) feeds upon the scale, both in its larval and adult state, and it is thought that there are also hymenopterous parasites.

Spraying with strong kerosene emulsion about July 1, when the newly hatched scales are detected moving about on the branches, is urged, the application to be repeated during the winter and again in the early spring.

A plate is given illustrating the San José scale for comparison with the plum scale.

Observations on insects—season of 1894, H. OSBORN and C. W. MALLY (*Iowa Sta. Bul. 27, pp. 135–149*).—This bulletin comprises notes on the chinch bug, western onion thrips, squash borer, and melon louse, and was in great part presented before the section on entomology of the Association of American Agricultural Colleges and Experiment Stations at its meeting in Washington in November, 1894 (E. S. R., 6, p. 265).

The chinch bug was destructive over much of the State, and especially so in the southeastern portions. An extended drought the preceding year assisted in the outbreak by favoring the hibernation of the bugs. Wheat, barley, rye, oats, and corn were all attacked to varying extents. The most damage was done where winter wheat had been cropped for some years before, and it is believed that the bugs were favored in their hibernation by the presence of osage hedges. Experiments with the chinch bug fungus diseases were not altogether satisfactory, although they were successful in a number of cases. Energetic treatment is urged to avoid extensive damage this year. Burning over every possible place for hibernation in the fall and early winter is advised, and the plowing of dusty furrows about the fields liable to be attacked. Planting trap strips of grain to attract the bugs, where they may be destroyed by spraying with kerosene emulsion, is also advised.

The western onion thrips (*Thrips alii*) was quite destructive in the State, feeding also upon various other plants besides onions. Several generations developed during the year, attacking the plants by gouging or corroding the surfaces of the stems and causing the leaves to wilt and droop. The insects collected in the axils of the leaves, where they were sheltered, and the eggs were deposited in the leaf substance. Spraying with kerosene emulsion, as soon as the young thrips are hatched, is advised, a second and third application to be given at intervals of from 3 to 5 days. The use of bisulphid of carbon was successful, but possesses drawbacks in the way of trouble and time involved. Destruction of the onion tops by burning as soon as the crop is harvested, is advised. Another allied species of thrips also appeared and caused some slight damage.

The squash borer is described and its life history briefly given. Heavy fertilizing, planting of extremely early and late varieties, collecting the moths by hand in the evenings, destroying badly infested vines, and covering the basal joints of the vines with earth are recommended as remedial measures.

The melon louse was quite damaging throughout the State, destroying many acres of melons and cucumbers, chiefly in August. Its life history is briefly noted, and spraying with diluted kerosene emulsion is recommended, the vines being lifted and the spray applied to the under surface of the leaves as well as to the upper. Experiments were made with different quantities of bisulphid of carbon, applied against the lice for varying times, and the details and results are tabulated. The insecticide was evaporated from small watch glasses or shallow tins placed by the plants, which were covered severally with washtubs, hay caps, and muslin. The muslin coverings proved insufficient to retain the fumes and the general results of the experiments were not altogether satisfactory, in several instances the lice surviving exposure to the fumes for an hour. Experiments were also made with hydrocyanic acid gas, generated in a small dish, and the plants covered for varying lengths of time. These experiments were very successful and the treatment is recommended for effectiveness and cheapness.

The use of bisulphid of carbon and hydrocyanic acid gas on low-growing plants, H. GARMAN (*Kentucky Sta. Bul. 53, pp. 144–150, fig. 1*).—An account of experiments with the above chemicals on the melon louse and rose aphis. The carbon bisulphid was used by introducing a tablespoonful of the fluid under a tub inverted over a melon hill, which was left undisturbed for about an hour and a half. By this means the majority of the aphides were killed, while the vines were not injured. In experiments with hydrocyanic acid gas a small cloth tent 3 ft. in diameter at the bottom and about 3 ft. high was used. This was supported by means of stakes over the plants to be treated, and beneath it was placed a saucer containing 9 cc. of water and 3 cc. of commercial sulphuric acid. To this 3 gm. of potassium cyanid was added. It was found that 4 minutes was a sufficient length of time to kill all insects present, with the exception of mites, and the method is recommended as being quick and effective for exterminating insects on single plants. A rosebush infested with the rose aphis was sprayed with antinonnin, 1 gm. to 1 qt. of water, but the lice were not completely destroyed. Hydrocyanic acid gas was then applied for 10 minutes, killing the insects, but also injuring the leaves of the plant.

The use of arsenites on tobacco, H. GARMAN (*Kentucky Sta. Bul. 53, pp. 125–143, figs. 6*)—This paper was in main part read before the section on entomology of the Association of Agricultural Colleges and Experiment Stations at its meeting in Washington in November, 1894 (E. S. R., 6, p. 265). In addition to the paper as there presented is given a discussion of various forms of apparatus for spraying tobacco, 5 of them being figured. A cart sprayer is believed to be best, but for ordinary purposes some form of knapsack sprayer is recommended, preferably one with a force pump attachment. A nozzle that causes the poison to issue in a fine mist is to be preferred. Spraying with 1 lb. of Paris green to 160 gal. of water is advised, to be first done about July 4 and followed by about 2 subsequent applications at intervals of 2 weeks. At least 2 weeks must elapse between the last spraying and the cutting of the plants.

Spraying for codling moth, H. GARMAN (*Kentucky Sta. Bul. 53, pp. 119–125, fig. 1*).—The results of experiments in spraying apple trees with arsenicals to determine their value as effective means of combating the codling moth. Two trees of Janet, about equal size, were selected for the experiment, and one was sprayed 6 times with arsenical mixtures, once with London purple, and 5 times with Paris green, the applications beginning in July and continuing until after August 27. The adjoining tree was left untreated as a check. The apples which fell to the ground from both trees were picked up on 5 different dates and examined with reference to injuries by the codling moth and rot. From the sprayed tree were examined 834 fallen apples, of which only 19 per cent were free from rot. Of the rotten apples 67 per cent were injured by the codling moth, while 82 per cent of those not rotting were infested. Of the fallen apples from the check tree 27 per cent were rot free, of which 96 per cent were injured by the codling moth, while of the rotted apples but 92 per cent were damaged. Eight hundred and seventy-four apples were picked from the sprayed tree, of which 68 per cent were damaged by the codling moth, while of 816 apples picked from the check tree 81 per cent were injured by the insect.

The conclusions drawn are in favor of spraying with arsenicals for the moth, though the rot fungus is apparently not affected by the application. It is believed from the evidence that the codling moth avoids rotting apples. Apples from the sprayed tree were carefully analyzed by the chemist of the station, but no perceptible quantity of arsenic was discovered.

Insecticides, A. N. CAUDELL (*Oklahoma Sta. Bul. 15, pp. 29, 30*).—Notes on experiments against the squash bug (*Anasa tristis*) with various insecticides, using a combination of pyrethrum powder and kerosene emulsion, and also some odoriferous substances, namely, emulsions of the oils of tansy, cajeput, savin, and eucalyptus. Dusting the plants with lime and pyrethrum was also tried, but none of the remedies were effective.

Household pests, G. H. PERKINS (*Vermont Sta. Bul. 43, pp. 73–78, figs. 4*).—This consists of illustrated descriptive, life history, and remedial notes on the buffalo beetle (*Anthrenus scrophulariæ*), pitchy carpet beetle (*Attagenus piceus*), and clothes moths (*Tinea pelionella, T. biselliella*, and *T. tapetzella*). Benzin and bisulphid of carbon are recommended against all of the species.

Cabbage gall insect (*Gard. Chron., 17 (1895), p. 500, fig. 1*).—Description of *Centiorhynchus sulcicollis*, for which applying gas lime in autumn is recommended.

The reappearance of Pieris protodice, J. A. MOFFAT (*Rpt. Ent. Soc. Ontario 1894, pp. 61, 62*).—Mention of the occurrence of this species in Ontario, where for a number of years it has been superseded by *Pieris rapæ*, with a discussion of the causes of its previous disappearance.

Phylloxera of the vine, A. DESPEISSIS (*Agl. Gaz. N. S. Wales, 6 (1895), No. 1, pp. 13–29, figs. 31*).—The life history of the insect and remedial measures are discussed.

The leaf folder and leaf skeletonizer, H. OSBORN (*Trans. Iowa Hort. Soc. 1893, pp. 174–176*).—Brief notes on *Teras minuta* and *Pempelia hammondi*, spraying with the arsenites being advised.

The gypsy moth, J. FLETCHER (*Rpt. Ent. Soc. Ontario 1894, pp. 67–72, figs. 4*).—A popular discussion of the insect, its life history, damage, and remedies, with an account of the methods employed against it in Massachusetts. Spraying with arsenate of lead is chiefly recommended.

Catastega aceriella, T. W. FYLES (*Rpt. Ent. Soc. Ontario 1894, p. 46*).—Description of the adult form of this maple moth, with brief notes on its habits.

An attack of Ephestia interpunctella, H. A. STEVENSON (*Rpt. Ent. Soc. Ontario 1894, p. 57*).—A brief note on the larva of this moth feeding on raisins. The attack was checked by the use of carbon bisulphid.

Pitcher plant moth, J. FLETCHER (*Rpt. Ent. Soc. Ontario 1894, pp. 44–46*).—Descriptive and life history notes on *Exyra rolandiana.*

Notes on a few Canadian Coleoptera, H. HARRINGTON (*Rpt. Ent. Soc. Ontario 1894, pp. 47–49*).—Brief notes on 21 species of beetles, several of economic value being among the number.

The San José scale, J. FLETCHER (*Rpt. Ent. Soc. Ontario 1894, pp. 73–76*).—Concise descriptive, life history, and remedial notes on *Aspidiotus perniciosus,* kerosene emulsion being given as the best remedy.

Injurious fruit insects of the year 1894, J. FLETCHER (*Rpt. Ent. Soc. Ontario 1894, pp. 76–81, figs. 7*).—Notes on a number of insects that were especially injurious in Ottawa the past season, particular mention being made of the pear tree psylla (*Psylla pyricola*), the apple cigar-case bearer (*Coleophora fletcherella*), an otiorhynchid (*Anametis grisea*), and the spotted paria (*Paria sexnotata*). The psylla was injurious for the first time and is recommended to be treated by means of kerosene emulsion.

Critical catalogue of the myrmecophilous and termitophilous Arthropods, E. WASMANN (*Berlin: F. L. Dames, 1894*).—An important work on the subject in all its bearings.

Kerosene attachment for knapsack spray pumps, H. E. WEED (*Garden and Forest, 8 (1895), p. 187, fig. 1*).

The economic value of parasites, F. M. WEBSTER (*Rpt. Ent. Soc. Ontario 1894, pp. 58–61, figs. 3*).—This paper was read before the section on entomology of the Association of American Agricultural Colleges and Experiment Stations at its meeting in 1894 (E. S. R., 6, p. 266).

Psilura monacha and its bacteria, A. METZGER and N. J. C. MÜLLER (*Mundener Forstliche Hefte. Berlin: J. Springer, 1895*).

Sixth annual meeting of the Association of Economic Entomologists (*Rpt. Ent. Soc. Ontario 1894, pp. 82–112*).—An abridged account of the proceedings and papers of the meeting, some of the papers, however, being printed in full. The proceedings were published at length in Insect Life, vol. VII, No. 2 (E. S. R., 6, p. 650).

FOODS—ANIMAL PRODUCTION.

Miscellaneous analyses of feeding stuffs, H. SNYDER (*Minnesota Sta. Bul. 36, pp. 129–145*).—The averages are given for analyses made at the station of the following materials, and calculation of the digestible materials in the same: Clover hay, pea hay, vetch, timothy hay, blue grass hay, millet, mixed prairie hay, upland prairie hay, blue joint hay, sedge grass, oat hay, corn fodder, wheat straw, oat straw, barley straw, clover straw, green rape, pasture grass, green clover, corn silage, sugar beets, mangel-wurzels, millet seed, barley, corn, oats, peas, rye, wheat, "goose" wheat, flaxseed, corn meal, corncobs, cotton-seed meal, gluten meal, germ meal, linseed meal, oat feed, wheat bran, wheat shorts, wheat germ, wheat flour, wheat screenings, and cockle bran.

An explanation is given of the terms used, the method of calculating the nutrients in a ration, and the fuel value of feeding stuffs. The amounts of nutrients furnished by one dollar's worth of a variety of feeding stuffs at local prices is shown in the following table, which is taken from the bulletin:

Digestible nutrients and heat units bought for one dollar.

Kind of feeding stuff.	Price.		Digestible nutrients.				Fuel value.
	Per ton.	Per bushel.	Dry matter.	Protein.	Ether extract, mainly fat.	Nitrogen-free extract and fiber.	
			Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Calories.*
Bran	$12.00	....	100	20	6	71	194,610
Bran	15.00	....	80	16	5	56	155,045
Corn meal	18.00	....	87	10	3	74	168,915
Corn meal	12.00	....	132	15	5	112	257,345
Corn and cob meal	15.00	....	100	10	3	86	191,235
Corn, shelled	....	$0.50	87	9	3	75	168,915
Wheat shorts	12.00	....	111	17	4	90	216,029
Wheat shorts	16.00	....	85	12	3	70	165,195
Oats	....	.30	72	10	4	56	139,760
Linseed meal	28.00	....	51	19	5	24	91,105
Linseed meal	24.00	....	59	23	6	28	120,210
Barley	....	.48	71	9	2	59	134,930
Peas	....	1.00	48	12	3	36	101,955
Peas	....	.70	68	16	4	49	137,900
Gluten meal	22.00	....	71	22	6	43	146,250
Cotton seed meal	28.00	....	47	23	7	14	97,395
Wheat	....	.50	87	14	2	70	155,987
Timothy hay	8.00	....	127	9	3	108	230,295
Prairie hay	6.00	....	163	11	4	138	294,040
Clover hay	10.00	....	105	15	3	82	193,095
Millet hay	8.00	....	138	10	3	121	256,236
Rye	....	.45	88	13	2	72	166,550

Popular information is given for using the above table in selecting feeding stuffs, and remarks on the factors which influence the composition of crops. Under the latter topic analyses are given of timothy cut at 3 different stages to show the effect of stage of growth on composition. A sample of timothy weighing 25 lbs. was exposed to 1 heavy shower and 3 heavy dewfalls. At the end of 5 days the hay weighed 21.5 lbs. The percentage of each nutrient lost by exposure was, ash 17.26, fat 7.47, protein 7.69, fiber 0.20, nitrogen-free extract 25.78. "The rain removed 12 per cent of the best part of the dry matter of the hay. . . In actual haymaking the loss would have been larger, because some of the hay would have been lost mechanically."

The digestibility of wheat, H. SNYDER (*Minnesota Sta. Bul. 36, pp. 146–148*).—The digestibility of wheat was determined by feeding it to young pigs (1) whole in connection with cracked corn and (2) cracked in connection with corn. Only the average results of the trials are given, which are as follows:

Digestion coëfficient for whole and cracked wheat fed to pigs.

	Whole wheat.	Cracked wheat.
	Per cent.	*Per cent.*
Dry matter	72	82
Ash	44	50
Ether extract (fat)	60	70
Protein (gluten)	70	80
Fiber	30	60
Nitrogen-free extract	74	83

"The results show a difference of 10 per cent digestibility in favor of the cracked wheat. Had the wheat formed more than half of the ration, the difference in digestibility would undoubtedly have been even greater.

"[The above coëfficients are compared with those for cracked barley, wheat, shorts, wheat bran, and cracked corn.]

"The digestibility of cracked wheat compares very favorably with other grains. It does not appear to be quite as digestible as corn, but the dry matter is more digestible than that of barley, shorts, or bran."

When the wheat was fed whole some of the kernels passed the animals undigested. These kernels were washed in distilled water and analyzed, the result being compared with the composition of the wheat as fed.

"The only noticeable difference is about 2½ per cent more water in the wheat recovered from the manure. When the results are compared on the basis of the dry matter the difference in composition between the 2 samples is very slight."

The digestible dry matter and nutrients in a bushel of wheat and of corn are compared as follows:

Digestible nutrients in a bushel of wheat and corn.

	Dry matter.	Fat.	Protein.	Carbohydrates.	Fuel value.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Calories.*
Wheat	43.5	1.0	7.0	35.0	82,345
Corn	43.5	1.5	4.5	37.5	84,407

"When wheat and corn are both selling at 50 cts. per bushel the 50 cts. will purchase the same amount of digestible dry matter of either wheat or corn, but the digestible dry matter in the bushel of wheat contains 2½ lbs. more of digestible protein, while the bushel of corn contains 2½ lbs. more of digestible carbohydrates. The amount of heat units produced by each grain is about the same. . . .

"Furthermore, the manure from the wheat is worth about 25 per cent more than the manure from the corn."

Corn on the cob and corn meal, W. P. WHEELER (*New York State Sta. Rpt. 1893, pp. 235-237*).

Synopsis.—A comparison of corn meal with ear corn on 2 lots of 4 pigs, lasting 63 days. The lot on corn meal made the larger and more economical gain, both financially and for the dry matter eaten.

Eight pigs, Poland China-Duroc cross, weighing about 110 lbs. each, were divided into 2 lots with 2 sows and 2 barrows in each. Both lots received the same amount of a grain mixture (5 parts wheat bran, 3 of cotton seed meal, 1 of linseed meal, and 1 of middlings), and in addition one lot had all the ear corn it would eat and the other lot had an equivalent amount of corn meal. Eighty-nine per cent by weight of the ear corn was kernels. The trial lasted from February 13 to April 17, being divided into 2 periods. The average results follow:

Comparison of corn meal with ear corn on pigs.

Lot.	Food.	Average daily gain in weight.	Food eaten per 100 lbs. live weight per day.		Dry matter eaten per pound of gain.	Cost of food per pound of gain.
			Total.	Dry matter.		
		Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Cents.*
E	Corn meal:					
	First period	0.75	2.48	2.06	2.75	3.43
	Second period	.70	2.21	1.84	2.63	3.26
F	Corn on the cob:					
	First period	.56	2.65	2.27	4.05	4.11
	Second period	.48	2.22	1.90	3.96	3.96

In estimating the cost of food corn is rated at $15 and corn meal at $20 per ton.

"At the close of the trial the average weight for lot E was 173.4 lbs. and for lot F 155 lbs. The gain made by lot E cost for the first period 16.5 per cent less than that made by lot F and during the second period 17.7 per cent less."

Is it advantageous to feed wheat and rye instead of the bran from the same? A. EMMERLING and P. JENSEN (*Landw. Wochenbl. Schles. Holst., 44 (1894), Nos. 45, pp. 619, 620; 48, pp. 667, 668; 49, pp. 684, 685*).—A controversy as to whether it is most advantageous from a financial standpoint to sell wheat and rye and buy bran for feeding. Emmerling, in the first paper, calculates the value of the digestible nutrients in wheat and bran and concludes that with wheat at 86 cts. per bushel and bran at about $17.25 per ton, the Hamburg prices, it is advisable to sell wheat and buy bran, and states that the same would apply to rye. Jensen criticises his taking Hamburg prices instead of Kiel, and contends that at the local prices for wheat and bran the calculations show the farmer can better afford to feed his wheat than to draw it to market and buy bran.

Emmerling recalculates the values on the basis of prices at a number of points and insists that farmers reasonably convenient to depots are warranted in selling the grain and buying bran.

The source of fat in milk, P. COLLIER (*New York State Sta. Rpt. 1893, pp. 156–173*).—This article opens with a discussion of the mechanism and chemistry of digestion, and of the theories of the formation of fat from albuminoids in the food. Data for the fat in the food and in the milk in the 90-day breed test at the World's Fair are presented, of which the following is a summary:

Fat in food and in milk in World's Fair breed test.

Breed of animals.	Fat eaten.	Fat digested.	Fat in milk.
	Pounds.	*Pounds.*	*Pounds.*
Jerseys	3,884.2	2,706.2	3,516.1
Guernseys	3,756.6	2,486.2	2,784.6
Shorthorns	4,101.1	2,932.6	2,410.0
Total	11,741.9	8,125.0	8,710.7

"It appears that there was upon an average 7.2 per cent more fat recovered in the milk than was digested in the food fed."

The total and digestible fat were calculated from average figures for composition and digestibility of the feeding stuffs used. It is calculated that had the percentage of digestible fat in the concentrated food been 0.38 per cent higher "it would have been sufficient to meet all the demands upon the animals for the fat produced in the milk and the increase in live weight of the animals during the trial."

The results for 1893 of the test of breeds at the station are next cited. It is shown that 23 cows in their first period of lactation, 18 in their second, and 10 in their third consumed the following amounts of food nutrients and produced the following amounts of fat in milk:

Food nutrients eaten and fat produced in milk.

Number of cows.	Period of lactation.	Nutrients eaten.				Fat produced in milk.
		Albuminoids.	Carbohydrates.	Crude fat.	"Pure" fat.	
		Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
23	First	22,911.20	113,388.10	9,958.90	8,226.10	6,810.20
18	Second	14,063.10	68,023.70	6,454.70	5,331.60	4,363.20
10	Third	6,733.60	30,964.70	3,166.50	2,615.50	2,272.00
	Total	43,707.90	212,556.50	19,580.10	16,173.20	13.445.40
	Ratio	3.25	15.81	1.46	1.20	1.00

"There was during these three periods an average increase of 161 lbs., or a total of 3,134 lbs. in the live weight of the animals under experiment, and if we assume the estimate of 8.7 per cent as the amount of fat represented in this gain it will amount to 272.7 lbs., which, added to the fat of the milk, will give 13,718.1 lbs. as the fat produced by these animals.

"If now we allow the crude fat of the food to contain 17.4 per cent of impurities, there would remain 82.6 per cent, or 16,173.2 lbs. of pure fat in the food eaten by these animals, or 18 per cent more fat than was produced by them in their milk or increase in weight. This will present a loss of 15.3 per cent of the pure fat through lack of digestibility, a loss greater than appears to exist in many experiments made. . . .

"It would seem that until strong proof shall be submitted that the fat of milk is derived from other constituents of the food its source at present must be held as the fat present in the food of the animal.

"It is proposed to make other experiments the coming season to clear up this point, if possible."

Effect of fat on the utilization of the albuminoids of the food, R. LAAS (*Ztschr. physiol. Chem., 20, No. 3, pp. 233–248*).—In 2 experiments dogs were fed on horse flesh freed from fat as far as possible, a quantity of fat being added to this in a second period. The results are believed to warrant the conclusion that the utilization of the albuminoids of the food is increased by the addition of fat—*i. e.*, more nitrogen was stored in the body on a constant ration of nitrogen when fat was added. Accompanying this no diminution in the decomposition process in the intestines could be detected. In this respect the action of fat is unlike that of carbohydrates, which have been found to materially decrease the splitting up of the albuminoids in the intestines.

On the question of the formation of fat from albuminoids in the animal body, M. KUMAGAWA (*Mitt. med. Fac. k. Jap. Univ., Tokyo, 3 (1894), p. 1; abs. in Chem. Ztg., 19* (*1895*), *No. 16, Repert., p. 58*).—The author's experiments were on dogs. They indicated that the animal body is not capable under normal conditions of forming fat from albuminoids. When albuminoids are fed in such large quantity that they alone more than fulfill all the food requirements of the animal, the decomposition of the nitrogen-free materials of the food nearly ceases, and the fat and the carbohydrates of the food are almost completely stored in the body as fat.

Soiling crops, 1894, J. WILSON (*Iowa Sta. Bul. 27, pp. 85–104*).—To test the value of a number of soiling crops, 6 cows, including 2 Holsteins, 2 Shorthorns, and 2 Red Polls, were fed from June 28 to August 28 a basal ration of 5 lbs. of hay and 9 lbs. of corn-and-cob meal per head daily, to which the following green crops were added in separate periods of 7 or 8 days: Peas and oats, red clover, fodder from sweet corn, soja bean, and cowpea. The supply of cowpea was so small that only 2 cows (Holsteins) could be fed upon it. The analyses are given of the soiling crops used, and tests of the composite samples of the milk. Data are also given for the yield of milk and butter, and the flavor, volatile fatty acids, and melting point of the butter produced on each soiling crop. The results are summarized below:

Average results with soiling crops.

Soiling crop.	Yield of milk.	Fat content.	Yield of fat.	Yield of butter.	Qualities of butter.		
					Flavor on basis of 45.	Volatile acids.	Melting point.
	Pounds.	*Per cent.*	*Pounds.*	*Pounds.*		*Cc.*	*Deg. C.*
Peas and oats	160	2.78	4.42	5.16	43	29.95	32.20
Red clover	155	2.96	4.59	5.35	43	29.90	32.60
Corn fodder	134	2.64	3.52	4.10	45		
Soja bean	130	3.08	3.99	4.65	45	28.95	33.00
Cowpea (cows Nos. 115 and 213)	54	3.16	1.69	1.97	43	28.70	32.50
Corn fodder (Nos. 115 and 213)	54	2.17	1.49	1.73			

As the cowpea was fed to only 2 cows, the data are given for these 2 cows while receiving corn fodder, for comparison.

> "The soja bean makes butter of a superior flavor; the creamery experts pronounced it equal to butter from corn. . . .
>
> "The cows did not eat it readily at first, but after getting it sprinkled with bran and salt for a few days they ate it readily. While getting accustomed to it the milk flow shrunk considerably, but at the end of the test period, August 19, they had reached a larger flow than at any time during the feeding of sweet corn, and, notwithstanding the shrinkage while getting used to it, the average daily yield of butter fat reached 3.97 lbs., and the last 4 days of the test went over 4 lbs. This shows the value of plants richer in protein than corn is."

The investigation of the several breeds of dairy cattle with reference to their relative value in the production of milk, butter, and cheese, P. COLLIER (*New York State Sta. Rpt. 1893, pp. 10–156, pls 4*).—The record of this extended investigation is continued from the Annual Reports of the station for 1891 and 1892 (E. S. R., 4, p. 255; 6, p. 68). The record includes 26 cows of the following breeds: Ayrshire, Jersey, American Holderness, Guernsey, Devon, Holstein, and Shorthorn. It covers for some of the cows a part of the first period of lactation, for others parts of the second and third periods, and for 2 cows parts of the third and fourth periods. The data given show for each cow the date of calving, and kinds and amounts of food eaten, the food ingredients eaten, the yield and composition of milk, yield of milk constituents, and general averages for each month of lactation; the relation of fat in the food to fat in the milk in each period of lactation, the cost of production of milk and fat, the percentage variation by months in food and milk constituents, comparisons of successive periods of lactation, and the relative size and number of globules in the milk of each breed in the different periods of lactation; and analyses of mixed hay, corn silage, corn fodder, alfalfa fodder, sorghum fodder, rye fodder, oat and pea fodder, beets, mixed grain, wheat bran, and oats fed in the trial.

Owing to the different periods of lactation in which the cows were, it is impracticable to give any concise statement of the results for the period covered which would not be misleading. The only discussion of the results in the report is with reference to the source of the fat in milk (see p. 1011).

Cotton-seed feed for dairy cows, H. P. ARMSBY and E. H. HESS (*Pennsylvania Sta. Bul. 28, pp. 22*).—"Quite recently there has been brought before the farmers of this State what is designated as 'cotton-seed feed,' which purports to be a mixture of 5 parts of the hulls with 1 of cotton-seed meal by weight. The result is a very bulky feed, weighing about 13 lbs. per bushel, which is offered at the price of $11.50 per ton in bulk in car lots at any point in Pennsylvania."

Analyses of 4 samples of this material and the computed composition of a mixture of 1 part of cotton-seed meal to 5 parts of hulls are given, as follows:

Composition of cotton-seed feed.

Constituents.	Computed 1 to 5.	Sample No. 14510.	Sample No. 15966.	Sample No. 16034.	Sample No. 16562.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Water	13.07	13.07	13.07	13.07	13.07
Ash	3.28	2.45	3.39	2.55	2.92
Albuminoids } Protein	10.05	6.92	9.51	7.21	10.25
Non-albuminoids } Protein		.88	.75	1.22	.40
Crude fiber	36.61	43.28	33.12	32.54	34.31
Nitrogen-free extract	33.22	30.67	36.77	40.66	36.01
Fat	3.77	2.73	3.39	2.75	3.04
Total	100.00	100.00	100.00	100.00	100.00

The cost of a mixture of 1 part of cotton-seed meal to 5 parts of hulls is reckoned at $10.42 per ton, plus the cost of mixing.

The digestibility of cotton-seed feed was determined in an experiment with 3 steers. This material was fed alone from March 23 to

April 21, the excreta being analyzed during the last 7 days. The results, together with those obtained at the North Carolina Station with 2 mixtures of cotton seed meal and hulls, are given, as follows:

Digestibility of cotton-seed feed.

Constituents.	Pennsylvania experiments.				North Carolina experiments.	
	Steer 1.	Steer 2.	Steer 3.	Average.	1 of meal to 6 of hulls.	1 of meal to 4 of hulls.

Upon the basis of the above data the digestible food ingredients in 100 lbs. of material, and the cost of the digestible materials (reduced to starch equivalent) in a number of common feeding stuffs, are computed.

"Both as regards bulk, chemical composition, and proportion of digestible matter the cotton-seed feed corresponds more nearly to a coarse fodder than to a grain feed. The results of our digestion experiments show it to contain rather less total digestible matter than either clover or timothy hay and a little more than good corn fodder. It has, however, a somewhat larger proportion of protein than either corn fodder or timothy hay but less than clover hay. In proportion to the amount of digestible matter which it contains it is a relatively expensive feed, costing more per pound of digestible matter than any of the feeds named in the table with the exception of cotton-seed meal. The indications of the digestion experiments, therefore, are that the feed contains only a moderate amount of actual food and that it is too costly to compete with more familiar feeding stuffs."

Two feeding trials were made to test cotton-seed feed, each with 2 lots of 3 cows each. In the first trial a ration of 8 lbs. of bran and cotton-seed feed *ad libitum* was compared with one of 7 lbs. of corn meal, and 3 lbs. of cotton-seed meal with corn fodder and clover hay *ad libitum*. These were fed in 2 alternating periods of 21 days. The milk was weighed and composite samples taken for testing. Some difficulty was experienced in inducing the cows to eat the cotton-seed feed.

The 2 rations contained practically the same amount of dry matter, but the cotton-seed feed ration contained considerably less digestible matter, owing to its low rate of digestibility. The average results of the trial are summarized in the following table:

Average results of comparison of rations on milch cows.

Ration.	Average daily yield.			Cost of food per pound of product.			Net profit per head daily.	
	Milk.	Milk solids.	Butter fat.	Milk.	Butter fat.	Butter.[1]

---

[1] Assuming 0.85 lb. of butter fat to make 1 lb. of butter.

The cost and profit are based on hay at $10, corn fodder $4, corn meal $18, cotton-seed meal $26, bran $14, and cotton-seed feed $11.50 per ton, butter at 25 cts. per pound, and skim milk at 20 cts. per 100 lbs.

"A ration of cotton-seed feed and bran produced 19 per cent less milk and 10 per cent less butter than one of corn fodder, mixed hay, corn meal, and cotton-seed meal containing an equal amount of dry matter.

"The feed cost per pound of milk was 13 per cent lower and per pound of butter 5 per cent lower on the hay and fodder ration than on the cotton-seed feed ration.

"The net profit per day and head was 17 per cent less on the cotton-seed feed ration than on the hay and fodder ration."

The experiment was repeated, using a second lot of cotton-seed feed. The general plan of the experiment was practically the same as the first, the lots being reversed on the rations. Each lot received 2 lbs. of bran and 6 lbs. of Buffalo gluten meal per head daily, and one lot had clover hay, while the other had cotton-seed feed *ad libitum* as coarse fodder. Four pounds of corn meal was fed to offset the cotton-seed meal in the cotton-seed feed, but this turned out to be too much, as the cows did not eat as much of the feed as was anticipated. From 9½ to 12½ lbs. of the cotton-seed feed was eaten daily, which would contain less than 2 lbs. of cotton-seed meal.

The average daily yield on the cotton-seed feed ration was 15.25 lbs. of milk and 0.763 lb. of butter fat, and on the clover hay ration 17.9 lbs. of milk and 0.814 lb. of butter fat.

"As in the former experiment, the cotton-seed feed ration produced less milk and butter than the ration with which it was compared. . . .

"The financial results of this experiment are slightly in favor of the cotton-seed feed ration, and thus apparently contradict those of the previous trial. It is to be borne in mind, however, that in this second trial the cotton-seed feed was compared with a heavier ration. . . .

"Plainly, however, the first method of comparison is the one best adapted to give a fair idea of the value of the new feed, and hence we shall give much more weight in our conclusions to the results of the first experiment."

The authors' conclusions are:

"(1) The results of these investigations indicate that cotton-seed feed is too expensive, in proportion to the amount of food which it contains, to successfully compete on equal terms with ordinary dairy foods at average prices.

"(2) The results of these experiments show that under average market conditions a very considerable profit may be realized by the conversion of dairy foods into milk and butter. The net profit over the estimated cost of feed and care in these experiments ranged from 77 to 95 per cent."

Pig feeding, different breeds, W. P. WHEELER (*New York State Sta. Rpt. 1893, pp. 224–234*).

Synopsis.—Two experiments in feeding young pigs of different breeds from birth until a little over 7 months old, in one case, and until 10 weeks old in the other. In the experiment for 7 months the average gain, cost of gain, and shrinkage in dressing were practically the same for all breeds. In the other experiment the Poland China and Berkshires made slightly the best gains, but the Duroc and the Duroc-Poland China cross the most economical.

The record is given for 8 Berkshires, 8 Poland Chinas, and 6 Poland China-Duroc cross fed from birth until a little over 7 months old, and for 3 Berkshire-Cheshire cross until 4½ months old. They were kept with the sows until they had learned to eat readily from the trough. They were fed skim milk, to which wheat bran was added during the first 4 weeks, a mixture of equal parts of bran and middlings during the next 5 or 6 weeks, and the same with increasing amounts of corn meal during the remainder of the trial. The nutritive ratio increased from about 1:2.5 at the beginning to about 1:5.8 at the close.

In calculating the cost of food bran is rated at $18, middlings at $20, and corn meal at $22 per ton, and skim milk at 25 cts. per 100 lbs.

"The average weight of the Berkshire pigs at beginning was 3.7 lbs., of the Poland China 2.9 lbs., and of the Poland China-Duroc cross 3.7 lbs. The average weight of the Berkshire-Cheshire cross was 2.1 lbs. At the close of the feeding trial, which lasted a little less than 7 months, the Berkshires averaged 198.8 lbs. in weight, the Poland Chinas 196.5 lbs., and the Poland China-Duroc cross 197.8 lbs. All the pigs were entirely healthy throughout the trial. The cost of all gain made for the whole trial, was for the Berkshires 3.82 cts. per pound, for the Poland Chinas 3.76 cts., for the Poland China-Duroc cross 3.80 cts.—practically the same for all. The Poland China pigs were ready to leave the sow about a week younger than the others. The Berkshire sow lost most in weight while suckling the pigs and the Poland China the least. The cost of food to restore the weight lost was for the Poland China sow 12.41 cts. per pound, for the Berkshire 5.88, and for the Duroc 4.96 cts. per pound. Six pigs from each lot were killed and dressed at the end of the trial and the average loss in weight by dressing was for the Berkshire 22.9 per cent, for the Poland China 21.8 per cent, and for the Poland China-Duroc cross 22.3 per cent. In the feeding experiment made the year before with Poland China, Duroc, and Berkshire pigs at a time when little skim milk was available and only grain was fed, the Poland China made a much more profitable growth than the others."[1]

The record is also given for a number of Poland Chinas, Berkshires, Durocs, and Poland China-Duroc cross fed for 10 weeks, being kept with the sows during the whole trial.

"For the first 5 weeks the food was skim milk and wheat bran, and for the next 5 weeks skim milk and mixed grain, consisting of equal parts of wheat bran and ground oats. . . .

"At the end of 10 weeks the average weights were 37 lbs. for the Poland China, 38.8 lbs. for the Berkshire, 31.1 lbs. for the Duroc, 33.6 lbs. for the Poland China-Duroc cross. . . .

"For the first period the gross cost of the gain made was least for the Poland China-Duroc cross, but considering the value of weight lost by the sow at the cost of afterwards restoring it, the Berkshire pigs made the most profitable gain. For the second period the gross cost of increase of weight was least for the Poland China-Duroc cross, and considering the cost of weight lost by the sow, the cost of the weight gained was least for the Durocs."

Pig feeding, wet and dry feed, W. P. WHEELER (*New York State Sta. Rpt. 1893, pp. 219–223*).

Synopsis.—Two trials to compare the same grain food when fed dry and when soaked. In the first trial both lots of pigs had the same quantity of food, but in the second it was given *ad libitum*. In the first trial the gains were the same on wet and dry feed, but in the second the lot on soaked grain ate a little more and made a slightly greater and more economical gain.

First trial (pp. 219–221).—Fourteen pigs, Poland Chinas, Berkshires, and Durocs, averaging 138 lbs. each, were divided into 2 lots and fed like amounts of food from June 8 to September 4. The food for lot A was mixed with 2 or 3 times it weight of water and allowed to stand 24 hours before feeding, while that for lot B was fed dry. It consisted of corn meal and a mixed grain, which was varied as the feeding advanced. Water was kept before both lots. The results for each lot are tabulated, based on the average per day per 100 lbs. live weight.

---

[1] E. S. R., 6, p. 70.

"The total gains made by each lot for the whole trial were almost exactly the same—549 lbs. for lot A and 548 lbs. for lot B. The total food consumed was the same for each lot. Considerable more water was taken by the lot having the wet food. . . .

"The wet food for lot A was always eaten very much faster. . . .

"The average loss in dressing for market was 22.8 per cent for lot A and 22.2 per cent for lot B—practically no difference."

The lot on dry food made the steadier gain.

Second trial (pp. 222, 223).—In this 2 lots of 8 pigs each were used, averaging 133 lbs. in weight, and including Poland Chinas, Berkshires, Durocs, Chester Whites, and a Berkshire-Cheshire cross. The food consisted of corn and a mixture of wheat bran, cotton-seed meal, linseed meal, and middlings, and was fed *ad libitum*. The trial lasted from February 9 to April 13. The results are tabulated as for the first trial.

"The hogs in lot D having the food which was mixed with water and soaked about 24 hours ate a little more than those in lot C having dry food, and made a slightly more economical gain, the cost of the gain in weight being 4.7 per cent less than for the lot having dry food. Lot D took a very little more corn meal in proportion to the mixed grain than did lot C, and the nutritive ratio of their ration was very slightly broader in consequence.

"There was an excessive quantity of food taken by the hogs in both lots, and 2 hogs in lot D suffered from indigestion, etc., after the close of the trial, and 1 (Duroc) died from congestion of liver following indigestion. The increase in weight, as in the first feeding experiment, was less regular with the lot having wet food. . . .

"After the close of the feeding trial the average loss in dressing 5 hogs from lot D was 24.2 per cent, and the average loss in dressing the 8 hogs in lot C was 22.9 per cent."

Horse feeding, R. WARINGTON (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893–'94), pp. 188–196*).—In this article the author gives a concise review of the experiments by A. Müntz on the horses of a tramway company in Paris, those by Grandeau and Leclerc (still in progress) on the horses of a cab company, and those of Wolff at Hohenheim, upon which "nearly the whole of our exact knowledge of horse feeding depends."

Some of the difficulties in the way of arriving at certain fixed data to guide in horse feeding are enumerated.

"Horses are not so generally alike in their powers of digestion, nor in the use they make of food, as a flock of sheep or a herd of cattle. This is, perhaps, partly because the sheep and cattle are always in repose, while the horse being worked to the full extent of his powers any individual weakness becomes apparent. The horse, too, is kept in work till old age, and we consequently have to deal with him both in strength and feebleness. Baudement placed 168 of the French cavalry horses on the same rations and studied the alterations in weight of each horse; he found that horses which were above the mean height, above the mean weight, and below the average age gave the best return for the food consumed."

With reference to the use of coarse fodders the author says:

"Although bulky foods, such as hay or straw chaff, are necessary ingredients of horse rations, a horse is by no means so capable of digesting vegetable fiber as an ox or sheep; the horse. in fact, is not provided with the digestive apparatus belonging to ruminant animals. In Wolff's experiments at Hohenheim, in which the same diet was supplied both to a horse and sheep, the horse succeeded worst in his digestion of the fiber of straw chaff, of grass, and of meadow hay, while in the case of clover and lucern hay he nearly equaled the sheep in digestive power. Wolff in his last report comes to the remarkable conclusion that the fiber digested by a horse is of no value, either as a means of sustenance while at rest or for the production of work. No direct proof of this is furnished; the conclusion is drawn from the lower nutritive and force-producing value of the digested matter of diets including hay. The conclusion has not been generally accepted, and the facts will, perhaps, bear another interpretation."

Experiments on the amounts of food required by a horse at rest, with only sufficient exercise to preserve health, are summarized.

"In Grandeau's experiments with meadow hay alone as the diet 3 horses were kept at rest for various times, amounting in all to 4 or 5 months each, half an hour's walking exercise being allowed per day. Each horse received 17.6 lbs. of hay per day, and this proved exactly sufficient to maintain their weight unaltered. The amount digested by each horse was determined through the whole period by analysis of the solid excrements. The 3 horses did not digest the hay equally well, and thus each horse was really nourished and its weight maintained by somewhat different amounts of food. The average result of 3 months' feeding for each horse was as follows:

Digestible matter required per day for maintenance of horses at rest.

	Live weight of horse.	Dry organic matter digested per day.	
		Actual.	Per 1,000 lbs. live weight.
	Pounds.	*Pounds.*	*Pounds.*
No. 2	897	5.90	6.57
No. 3	853	5.98	7.00
No. 1	806	6.31	7.82
Mean of 3 horses for 14 months			7.02

"Grandeau and Leclerc experimented with many other diets, but in only a few cases did their maintenance diets exactly meet the wants of the horse. The results in these cases are given in the next table, but the results with other diets are of far less authority than those obtained in the more extended experiments with meadow hay.

Dry matter in maintenance rations for horses.

Diet.	Weight of horse.	Dry organic matter per day.		
		In ration.	Digested.	Digested per 1,000 lbs. live weight.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*
Hay alone (mean)	868	14.08	6.09	7.02
Maize and oat straw	1.013	11.57	8.33	8.22
Maize, oats, hay, and straw	972	9.48	7.30	7.50
Do	906	9.49	6.74	7.45
Oats alone (crushed)	913	8.50	6.41	7.02

The minimum quantity of albuminoids required to replace the daily waste of the body, judging from the French experiments, must be extremely small. The 3 horses observed by Grandeau received, on an average, 0.538 lb. of digestible albuminoids per 1,000 lbs. live weight daily. But there is evidence that this is not the minimum amount, for one horse averaged only 0.447 lb. of digestible albuminoids per 1,000 lbs. live weight during 2 months, and gained 5 lbs. in weight; and in another case the same horse gained somewhat on a ration of 0.37 lb. of digestible albuminoids. In view of the data at hand, the author is inclined to regard about 0.45 lb. of digestible albuminoids per 1,000 lbs. live weight as the minimum quantity per diem for the maintenance ration of a horse. This makes the nutritive ratio very wide; in the case of the horse cited above it was only 1:12.8.

"Müntz studied the digestive functions of the horse by killing 2 of little value a few hours after they had been fed, and analyzing the contents of the stomach and of successive portions of the intestines separately. One horse had been fed on hay and one on wheat bran. It appeared that all ready-formed sugar was absorbed in the stomach. Starch did not disappear in the stomach; it is digested subsequently by the pancreatic juice. When the food consisted wholly of bran, more than half of the albuminoids and a considerable proportion of the cellulose disappeared in the stomach; but when the food consisted of hay, no assimilation of albuminoids, and scarcely any of cellular matter, took place in the stomach. It is difficult to tell what occurs shortly after leaving the stomach, owing to the large quantity of digestive fluids (bile and pancreatic juice) which are poured into the canal. The largest amount of absorption apparently occurs in the large intestines and colon, and it is here that the most striking diminution takes place in the various cellulose constituents."

In this connection the effect of labor on digestion, as shown by Grandeau and Leclerc's experiments, is interesting.

"Taking the mean of a very large number of experiments with different diets, and taking the proportion of organic matter digested while at rest as 1,000, we have the following series of figures as representing the proportion digested during different degrees of labor:

Relative proportion of food digested.

At rest	1,000
Walking exercise	1,032
At work walking	1,007
Trotting	976
At work trotting	973
At work in cab	959

"We see here that the moderate exercise is accompanied by a small but distinct improvement in the digestive functions, but that as soon as trotting commences digestion becomes less efficient than when at rest, while hard work while trotting still further diminishes the proportion of food digested. When we look into the details we find that the starch and sugar in the food are perfectly digested under all conditions of labor. The digestibility of the fat increases with exercise and does not diminish by labor below the point reached in repose. The digestibility of the albuminoids increases rather considerably with exercise and diminishes sharply when trotting commences. The principal matters usually grouped as 'soluble carbohydrates,' but which in this case are merely the more digestible constituents of the

> fiber, undergo the greatest amount of variation, their digestibility rising considerably with exercise and falling still more considerably with hard labor. In the case of the more insoluble portion of the fiber there is no rise in digestibility by exercise; the maximum rate of digestion is here obtained in repose, and diminishes considerably with increased bodily exertion. On the whole it appears that the constituents of the food which are most affected by rapid exertion are those whose digestion takes place to a large extent in the lower part of the intestines; the motion of the horse probably determines their more rapid passage through the system."

Grandeau's experiments have brought out the marked influence of pace on the amount of labor performed and the food required.

> "Thus a horse walking 12½ miles per day was kept in condition with a daily ration of 19.4 lbs. of hay, while a ration of 24 lbs. of hay was insufficient when the same distance was done trotting. Again, a horse walking the above distance and dragging a load, the additional work being equivalent to 1,943 foot-tons, was sufficiently nourished by a ration of 26.4 lbs. of hay; but a daily ration of 32.6 lbs. (all that the horse would eat) was not enough to maintain the horse's weight when the same work was done trotting."

Some of the reasons mentioned why rapid work is less economical than slow work are the increased work of the heart when the horse is trotting or galloping; the lifting of his own weight at each step, only to allow it to fall again, developing heat; the increase of temperature with exertion, and the loss of heat by evaporation of water through the skin and lungs.

> "The mean quantity of water evaporated daily, under different conditions of exercise, as determined in experiments with 4 different diets, was as follows:

Water evaporated per day.

	Pounds.
At rest	6.4
Walking exercise	8.6
At work walking	12.7
Trotting	13.4
At work trotting	20.6

> "As already explained, the distance trotted was the same as the distance walked, and the load drawn when trotting the same as when walking. The heat consumed in the evaporation of water is very considerable; the loss of water in the breath and perspiration thus necessitates a consumption of food to produce this heat, and diminishes considerably the quantity of food available for the production of work."

As to whether a nitrogenous ration is or is not essential for horses at hard work, it is said that Grandeau's researches do not furnish any information, but that we have to rely chiefly on the investigations of Wolff and of Müntz.

> "The doctrine laid down by Wolff and his fellow-workers at Hohenheim is a very simple one. He distinguishes between the food necessary to maintain the horse at rest without loss of weight and the extra food which must be given when work is performed, if the horse is again to be maintained without its weight suffering loss. Between the weight of digestible matter in this extra food and the quantity of work accomplished there is a tolerably uniform relation. Wolff reckons that digested nutritive matter equivalent to 100 gm. of starch is capable of producing 85,400 kilogrammeters of work, or, expressed in English terms, 1 lb. of starch digested by a horse will accomplish 1,232 foot-tons of work. This is 48 per cent of the full work which

the starch could accomplish if burned outside the body. This result is the average of many experiments with different diets.

"The horse requires for his maintenance in weight while at rest a certain daily supply of albuminoid substance, which must never fall below a certain quantity; but the extra food given when work is to be performed may consist indifferently of any digestible combustible substance, whether albuminoids or not. The horse keeper is thus at liberty to select from a wide range of foods, and is not obliged to give a preference to those which are specially nitrogenous. It should, however, be borne in mind that what has just been said applies strictly only to horses which are already in good working condition. Horses which are low in condition, and must gain in weight of muscle before they are fit for hard work, must, of course, receive a more nitrogenous diet."

The author finds it impossible to state exactly the nutritive ratio of the rations fed by street railway companies in England, as the composition of the foods fed is not known definitely; but from the rations published he fixes the ratio at from 1:7 to 1:8.

Poultry, W. P. WHEELER (*New York State Sta. Rpt. 1893, pp. 214–219*).—The plan is given of a breeding experiment which has now been in progress for 2 years at the station, and a detailed statement of the cost of raising young fowls. About 130 Cochin and Leghorn chickens were hatched by the natural method, for the special purpose of obtaining pullets for use in a feeding experiment. Of the Cochin eggs set 46.1 per cent produced healthy chicks, and of the Leghorn eggs 75.2 per cent. Counting eggs at 24 cts. per dozen, and the food eaten by the sitting hens at local prices, the cost of each chick when hatched was 4.65 cts. for the Cochins and 2.82 cts. for the Leghorns. The hens were kept with the chickens from 5 to 6 weeks. The food of the growing chickens was cracked wheat, skim milk, desiccated beef, finely cut fresh bone, and mixed grain, which was varied from time to time. The chickens remained entirely healthy, and only a few were lost from accidents. The sexes were separated when the Cochins averaged 109 days old and the Leghorns 84 days. At that time the Cochins averaged 4.05 lbs. and the Leghorns 1.83 lbs. The average total cost per chick (including hatching) amounted to 24.36 cts., or 6.01 cts. per pound, for the Cochins, and 12.59 cts., or 6.88 cts. per pound, for the Leghorns.

The pullets of both breeds were fed 11 weeks longer, at an average cost per fowl of 20.07 cts. for the Cochins and 13.09 cts. for the Leghorns, at which time the Cochin pullets averaged 5.53 lbs. and the Leghorns 2.81 lbs. Deducting from the total cost to date the local market value of the cockerels at the time the chickens were separated gives the net cost of the Cochins at 13.24 cts. each and of the Leghorns 16.78 cts.

"The sexes were about equal with the Cochins, but there was an unusual excess in the number of pullets among the Leghorns hatched (37 per cent more pullets than cockerels), so that the poultry value of the cockerels represented a lesser proportion of the value of food consumed. Had the sexes been equal, at the same proportionate cost for growing, and considering the poultry value of the cockerels, the net cost of Leghorn pullets would have been 13.55 cts. apiece, nearly the same as that of the Cochins."

Human food articles (*Massachusetts State Sta. Bul. 57, p. 2*).—Analyses with reference to food ingredients of roasted oats, Hecker's oatmeal, rolled avena, and rolled oats.

Analyses of fodder articles (*Massachusetts State Sta. Bul. 57, pp. 3–5*).—Analyses of Canada hay, linseed meal, Chicago maize feed, wheat bran, corn products, oat feed, Atlas meal (dry distillery feed), and water grass (sedge), the last two with reference to fertilizing ingredients.

Does the palm-nut meal obtained in the extraction process contain carbon bisulphid or other objectionable substance? W. SONNE and A. SCHMIDT (*Ztschr. landw. Ver. Hessen, 1895, No. 10, pp. 73, 74*).—After describing the method by which the meal is obtained in the extraction of oil from palm nuts by carbon bisulphid, the authors mention 2 experiments with meal from a factory in Darmstadt. This meal was found to be entirely free from bisulphid or other similar substance of objectionable smell or taste.

Oleomargarin, a hygienic study, A. JOLLES (*Abs. in. Chem. Ztg., 19 (1895), No. 10, Repert., p. 32*).

Feeding stuff from peat and molasses, A. WAGNER (*German patent; Chem. Ztg., 19 (1895), No. 31, p. 713*).

Detection of adulterants in olive oil, A. MÜNTZ (*Bul. Min. Agr. France, 14 (1895), No. 1, pp. 89–126, fig. 2*).

Digestion of fat in the stomach, C. CONTEJEAN (*Arch. de Physiol.* [*5*], *6, I, p. 125; abs. in Centbl. Physiol., 8, p. 581, and in Chem. Centbl., 1895, I, No. 3, p. 164*).

Digestion products of casein and their phosphorus content, W. VON MORACZEWSKI (*Ztschr. physiol. Chem., 20, No. 1 and 2, pp. 28–51; abs. in Chem. Centbl., 1894, II, No. 23, p. 919*).

The nuclein resulting in the pepsin digestion of casein, J. SEBELIEN (*Chem. Ztg., 18 (1894), No. 102, p. 2018*).—A preliminary note.

How to make the most of the cow in winter, A. POTTIE (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893–'94), pp. 208–212*).—The author argues for warmer stables in winter, and gives the results of his experience and observation with thermometers. He recommends 63° F. as the proper temperature for a cow stable in winter. The cows not only give more milk, in his experience, but are kept in better condition than when the temperature is colder or much warmer. He cites two striking instances in which the milk yield of herds was materially increased and their condition improved by raising the temperature of the cold stables to about 63°.

Cattle feeding, W. P. WHEELER (*New York State Sta. Rpt. 1893, pp. 212–214*).—Remarks on the kinds of food fed in different parts of the year in the test of breeds of dairy cows.

Organized cottage poultry keeping, G. F. C. PYPER (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893–'94), pp. 71–82*).

VETERINARY SCIENCE AND PRACTICE.

Experiments with tuberculin on non-tuberculous cows, J. LAW (*New York Cornell Sta. Bul. 82, pp. 659–676*).—Five healthy cows, 3 of which were giving milk, received weekly full doses of tuberculin, and their temperature was taken every 2 hours, from 9 to 20 hours after injection, and compared with their normal temperature. These injections exercised no noticeable influence on the temperature of the animals, yield of milk, or on the percentage of fat in the milk. "There is nothing in the record of temperatures that would indicate, either at the time of the injection or later, that the tuberculin would prove inimical in any way. So far as there is evidence before us, everything points to the harmlessness of a single test dose on a sound system."

The temperature, yield of milk, and percentage of fat in the milk are tabulated for each animal used in the experiment.

Variability of Bacillus anthrax, A. CHAUVEAU and C. PHISALIX (*Compt. Rend.*, *120* (*1895*), *No. 15*, *pp. 801–807*, *fig. 1*).—A new variety is described, *B. anthracis claviformis*.

Reports of the veterinary colleges of Alfort, Lyons, and Toulouse (France), TRASBOT, ARLOING, and LAULANIE (*Bul. Min. Agr. France*, *14* (*1895*), *No. 1*, *pp. 59–89*).

Report of the Royal Commission on tuberculosis (*Nature*, *52* (*1895*), *May 2*, *pp. 19*, *20*).—A summary.

DAIRYING.

The treatment of milk in the stable (*Landw. Wochenbl. Schles. Holst.*, *45* (*1895*), *No. 11*, *pp. 169*, *170*).—Extracts from a talk by Prof. Fleischmann before a convention of coöperative creamery delegates. The lack of cleanliness in milking is emphasized as a most important cause of inferior dairy products. In Bavarian Algau the creameries forbid straining the milk and require that it be delivered just as milked, in order that they may judge of the cleanliness exercised in the stable by each patron. Their unstrained milk is without doubt cleaner and keeps better than the ordinary carefully strained milk of Schleswig-Holstein. It is stated that in Switzerland the milking is done with the bent thumb and first two fingers, so that the milk can not come in contact with the hand.

Another serious error mentioned is allowing the milk to stand in the stable after milking, and this is far greater where the milk is cooled there with a milk cooler, as is often done. The utmost cleanliness in the care of the cows and in milking is insisted upon as requisite to the finest quality of dairy products, and the further this is departed from the greater the difficulty in making good products. "All the results of scientific investigation which have found such great practical application in the treatment of diseased wounds, in disinfection, and in preserving various products are almost entirely ignored in milking."

Trials of cream-raising systems (*Jour. Bath and West of Eng. Soc.*, *ser. 4*, *4* (*1893–'94*), *pp. 200–207*).—Two series of trials were made under "very unfavorable conditions" to compare the separator (Alpha Baby, hand power), Jersey creamer, shallow pan, and scald cream method. In the latter the milk after being set was scalded on one of the milk scalders commonly used in Devonshire.

> "[The Jersey creamer] consists of a series of metal vessels in which the milk is set at a high temperature. These vessels are jacketed; that is, they have an outer coat which can be filled with water and through which a stream of cold water can flow. The vessels are provided with covers to keep dust from settling upon the cream, but so constructed as to permit of a free circulation of air above the cream. The skim milk is drawn off through a very fine metal sieve, which does not permit the cream to pass through it. When all the skim milk has been removed this sieve can be withdrawn and the cream collected in a separate vessel."

In each trial butter was made from the cream, and analyses of the butter are given. The proportion of the total fat in the milk which was recorded in the butter in the 2 trials was as follows: Separator, 88 and 87.5 per cent; Jersey creamer, 77.5 and 69 per cent; shallow pans, 81 and 78.5 per cent; scald cream, 76.5 and 65.6 per cent.

A fungus on butter, E. J. McWeeney (*Jour. Roy. Agl. Soc. England, ser. 3, 5 (1894), No. 19, pp. 567–569, figs. 5*).—The author describes and figures a fungus causing dark brown spots on butter.* It corresponds to a fungus said to infest the wood used for making butter boxes. It is not mentioned as troublesome as yet.

Observations on Cheddar cheese-making, F. J. Lloyd (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893–'94), pp. 131–176*).—A large amount of tabulated data obtained principally in connection with the Bath and West of England Society's cheese school, including the analyses of the milk, whey, curd, and cheese, together with some bacteriological observations previously referred to (E. S. R., 6, p. 481).

"The results of this year's work confirm in every particular the conclusions which have been come to in previous reports. It is scarcely necessary to reiterate the conclusions come to in this report.

"The work of three years may be summarized as follows:

"To make Cheddar cheese of excellent quality, one, and one single organism only, is necessary in the milk, that is the *Bacillus acidi lactici*; every other organism present will tend to make the work more difficult. Hence it is imperative that scrupulous cleanliness be the primary consideration of the farmer and of the cheese-maker, as of all those who have in the least possible respect to deal with the cows, the milk, or the apparatus employed.

"Secondly. No matter what system of manufacture be adopted, two things are necessary—two results must be obtained. The one is that the whey be separated from the curd, so that when the curd is ground it shall contain not less than 40 per cent of water, nor more than 43 per cent; and the other is that the whey left in the curd shall contain developed in it before the curd is put in the press at least 1 per cent of lactic acid if the cheese is required for sale within 4 months, and not less than 0.8 per cent of lactic acid if the cheese is to be kept ripening for a longer period.

"Lastly. The quality of the cheeses which comply with the foregoing standard will vary according to the quality of the milk from which they have been made, and, proportionately, to the amount of fat present in that milk. The fat is the constituent which most affects the quality of the cheeses; hence it is not possible to expect the same quality of cheese to be made from land which yields large quantities of poor milk as from land which yields small quantities of rich milk. But, with due care, the larger yield of cheese which can be obtained from the poorer milk should balance in value that of the higher quality which can be made from the richer milk-yielding pastures."

The sterilization of milk, A. Rodet (*Rev. Hyg., 1894, No. 12, p. 1025; abs. in Centbl. Bakt. und Par. Med., 17 (1895), No. 13–14, pp. 501, 502*).

Concerning butyric acid fermentation, E. Baier (*Centbl. Bakt. und Par. Allg., 1 (1895), pp. 17, 84, 118*).

The business side of the Babcock test, W. H. Jordan (*Rpt. Maine Bd. Agr. 1893–'94, pp. 109–117*).—A paper on the advantage of scientific methods in dairying and describing experiments at the Maine Station to investigate the value of the Babcock test to practical dairymen.

The manufacture of Cheddar cheese, T. C. CANDY (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893–'94), pp. 127–131*).—Detailed popular description of the author's method.

Experiments relating to the manufacture of Edam cheese, L. L. VAN SLYKE (*New York State Sta. Rpt. 1893, pp. 244–263, figs. 5*).—A reprint from Bulletin No. 56 of the station (E. S. R., 5, p. 211), with the addition of 4 figures showing press and salting molds.

Experiments relating to the manufacture of Gouda cheese, L. L. VAN SLYKE (*New York State Sta. Rpt. 1893, pp. 264–275, figs. 4*).—A reprint from Bulletin No. 56 of the station (E. S. R., 5, p. 211).

Study of the cheese-ripening process, L. L. VAN SLYKE (*New York State Sta. Rpt. 1893, pp. 276–285*).—A reprint from Bulletin No. 54 of the station (E. S. R., 5, p. 85).

Experiments relating to the manufacture of cheese from normal milk rich in fat, L. L. VAN SLYKE (*New York State Sta. Rpt. 1893, pp. 285–319*).—A reprint from Bulletin No. 54 of the station (E. S. R., 5, p. 85).

Character and extent of investigation made in relation to the manufacture of cheese in cheese factories during the season of 1893, L. L. VAN SLYKE (*New York State Sta. Rpt. 1893, pp. 319–486*).—A reprint of Bulletin No. 65 of the station (E. S. R., 5, p. 892).

Dairying from a business standpoint, G. A. BOWEN (*Rpt. Maine Bd. Agr. 1893–'94, pp. 95–105*).—A general paper recommending accurate and modern scientific methods.

Dairying at the World's Fair, J. GOULD (*Rpt. Maine Bd. Agr. 1893–'94, pp. 133–144*).—A paper briefly discussing the dairy exhibitions at the World's Fair and speaking of their value as public instructors.

General dairy practice, W. D. HOARD (*Rpt. Maine Bd. Agr. 1893–'94, pp. 118–128*).

The progress and conclusions of modern science as applied to practical dairying, W. D. HOARD (*Rpt. Maine Bd. Agr. 1893–'94, pp. 83–90*).—A popular paper on the subject urging the more extensive application among farmers of scientific methods in dairying, the testing of milk, careful feeding, and a systematic study of the herds.

Matzoon, H. J. PATTERSON (*Agl. Sci., 8 (1894), No. 10-11, pp. 447, 448*).—The analysis of this drink made from milk is given.

TECHNOLOGY.

Experiments with corn for brewing, C. SCHUBERT (*Allg. Ztschr. Bierbr. und Malzfabr., 22, p. 888; abs. in Vierteljahr. Chem. Nahr. und Genussmtl., 9, p. 406, and in Chem. Centbl., 1895, I, No. 7, p. 401*).—Experiments in the use of maize for brewing showed that the process was normal and a beer produced which could not be distinguished from normal lager beer by analysis, but had a peculiar taste. The latter is considered disadvantageous to the use of corn for brewing.

The silk industry in France, N. RONDOT (*L'Industrie de la Soie en France. Lyons: 1894, pp. 150*).—This is a comprehensive popular work, largely historical in character, tracing the development of the silk industry in France from the earliest times, and also treating briefly the different processes in the manufacture of silk goods of all sorts, including ribbons, tulles, etc., as well as dress goods. The author states that silk came to us from the Orient, and that Asiatic silk was woven in Europe long before the silkworm itself or the art of drawing threads from its cocoons was known to western peoples. About the middle of the 15th century the true history of silk making in

France begins, the art being in the beginning not so much a trade as a domestic art, mainly practiced by women. In three centuries this paltry industry has become not only one of the first in France but one of the first in the world.

The silk industry has two distinct branches, the first having for its object the production, the second the weaving, of silken threads. The first of these branches is conducted in 24 departments of France, nearly all in the southeastern part of the country, while the manufacture of various silk fabrics is conducted in several large cities, the most important being Lyons. The industry is much subdivided, and it is difficult to make any exact estimate of its proportions, but it is stated that probably 520,000 persons are engaged in it in some way, and that they divide annually 350,000,000 francs in wages and profits. France consumes three tenths of all the silk offered for sale in the world.

The history of silk weaving at Lyons, the most important center of the industry, is treated in chapter X. It started from very small beginnings, being here, as elsewhere, mainly practiced by women, who manufactured narrow strips of silk called tissu or tixu. The industry grew slowly in competition with Italian fabrics, but toward the end of the 18th century was fully established, and after being almost ruined by the French Revolution, revived again in greater vigor than before. A notable tendency of modern silk manufacture has been in the direction of making fabrics only partly of silk, instead of the pure-silk goods once almost exclusively made, the production of such mixed goods having risen from 23,000,000 francs in 1840 to 151,000,000 francs in 1893.

At present the outlook for the silk industry in France is uncertain. The disturbed state of business in general has had its effect here as elsewhere, and the increasing extent to which silk is being made in other countries has lessened to some extent the demand for the French products. Yet from the peculiar fitness of the French people for the delicate manipulations of silk culture and silk manufacture, and in view of the fact that the industry in France has survived other periods of stress, it is thought that French manufacturers of silk will be able by greater exertions to retain the ascendancy in the art which has so long been one of the glories of France. The volume concludes with some statistics (the date of which is not given) of the world's production and consumption of silk, by countries.—R. M. REESE.

Observations on cider making, F. J. LLOYD (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893-'94), pp. 98-106*).—An interesting account of experiments in cider making and fermentation.

Cider making, J. HARPER (*Jour. Bath and West of Eng. Soc., ser. 4, 4 (1893-'94), pp. 82-98*).—Detailed popular directions for making cider according to the most approved method.

Investigations on the viscosity of lubricating materials, etc., G. LUNGE (*Ztschr. angew. Chem., 1895, No. 7, pp. 189-191, fig. 1*).

The relation of bacteriology to tanning, F. H. HAENLIEN (*Centbl. Bakt. und Par. Allg., 1 (1895), p. 26*).

Palmetto extract, a new tanning material, SCHNIZER (*Chem. Ztg., 19 (1895), No. 9, p. 167*).

AGRICULTURAL ENGINEERING.

Water supply in Nebraska, O. V. P. STOUT (*Nebraska Sta. Bul. 41, pp. 153–172, map 1*).

Synopsis.—A preliminary report giving all available data relating to the flow of water in the principal streams of Nebraska and discussing the value of the North Platte, the Loup, Republican, Frenchman, South Platte, and Platte rivers for irrigation, with suggestions regarding storage of flood waters and the use of underground water.

In view of the general attention which has recently been directed to Nebraska as a field for irrigation development, the station "has undertaken the collection of facts and the investigation of conditions which have to do directly with irrigation in Nebraska, and the presentation of results and conclusions in a series of bulletins, of which this one may be considered a preliminary or introductory number."

All accessible data relating to the flow of streams in the State, including the results of gauging made under the direction of the station, are given in tables, and estimates, "as definite as the data will warrant, of the capabilities of each stream to supply a perennial flow to canals," are made. A map shows the location of proposed and completed irrigation ditches in Scotts Bluff and Cheyenne counties, along the course of the North Platte River.

> "Complete statistics as to the whole amount of land now under ditch in the valley of the North Platte are not at hand, but it is believed to be considerably in excess of 200,000 acres. Under constructed ditch, and under survey with prospect of construction, there are at least 600,000 acres."

From the data thus far collected it is estimated that the total minimum summer flow of this river available for irrigation is 3,150 second-feet and that this in connection with the flood water for which storage facilities are being provided is sufficient for the 600,000 acres included in the various irrigation enterprises in this valley.

> "The Loup River, with its several branches and tributaries, is next in importance to the North Platte as a source of supply for irrigating canals. The need for irrigation of the lands which it may water is not, however, so imperative as in the case of the North Platte, but . . . here, as elsewhere in Nebraska, outside the eastern counties, some form or method of irrigation must be devised and put into operation if the agricultural population is to have guaranty of a secure living."

The flow of these streams is very constant, due to the return of seepage water, but the data thus far collected are not sufficient to furnish a safe basis for estimating their capacity for irrigation. Only "the Middle and North Loups, and the main stream below their confluence, present favorable conditions for irrigation development." In other parts of this river system the valleys are so narrow and the adjacent table-lands so high "that even where it is physically possible it is rarely financially practicable or advisable to lead the water to such table-lands."

The Republican River goes dry nearly or quite every summer, and hence can not be relied upon for irrigation. The Frenchman River, however, which flows into the Republican, like the Loup has a steady flow and is being utilized to its full capacity. The area under ditch in the Frenchman and Republican valleys is estimated at a little over 50,000 acres. "The information concerning acres actually irrigated is not complete enough to constitute a basis for a reliable estimate, but the number falls far short of the number of acres under ditch."

Little definite data regarding the Platte and South Platte rivers are given except that "canals of capacity sufficient to utilize the entire amount in dry years are already constructed," and that while the flood value of the Platte is immense the summer flow is very uncertain.

The storage of the flood waters is urged and some of the difficulties encountered in such storage are pointed out.

> "The rather discouraging light in which the subject of storage in ponds, lakes, or reservoirs presents itself causes us to turn in another direction as we seek to prevent the flood waters from passing by unused. In the development of one of the most attractive projects now under consideration in the State it is proposed to place entire dependence upon flood water, which is available in great quantity and is practically all that is available. It is proposed to prepare the subsoil of the fields to receive the excess of water which can be furnished at flood period, and to hold it there until it is needed and drawn up by the crops in the dry part of the growing season. The recorded experience of many years in many countries goes to show that a properly prepared subsoil is efficient as a conserver of moisture, and as previously noted, the results of experiments already made encourage the belief that Nebraska soil will prove to be exceptionally efficient in this way."

The utilization of the underground water supply is discussed.

> "Irrigation by pumping from wells has not yet been practiced to any great extent in Nebraska. It is almost certain, however, that within the next few years nearly every farmer in the western and middle part of the State, where conditions are at all favorable, will have from 2 to 15 acres under irrigation by this method."

Detailed information on this subject is to be published in a future bulletin of the station.

Progress of irrigation (*Jour. Frank. Inst., 139 (1895), No. 832, pp. 310–312*).—A summary.

Wide tires, R. STONE (*U. S. Dept. Agr., Office of Road Inquiry Bul. 12, pp. 5–16*).—This bulletin includes extracts from State laws, accounts of experiments with wide tires, opinions of correspondents, newspaper notes, and statements regarding the width of tires prescribed by law in various foreign countries. The evidence appears to be overwhelmingly in favor of the adoption of wider tires than are now in general use.

Construction and ventilation of dairy barns, C. F. CURTISS (*Iowa Sta. Bul. 27, pp. 109–112, figs. 2*).—The construction of a barn 40 by 70 ft. in size and costing $4,000 is described, the special feature consisting in the construction of the ventilators, for which purpose the hay chutes and some of the spaces between the studding of the outer wall and between some of the rafters are utilized.

An underground silo, W. W. COOKE and F. L. WATROUS (*Colorado Sta. Bul. 30, pp. 21–23*).—A silo with a capacity of 64 tons was built on the station farm at a cost of 43 cts. per ton of capacity, or 65 cts. per ton including the cost of partitions for 4 compartments. On a spot which remained dry the whole year a hole 21 ft. square and 8 ft. deep was dug, chiefly with scraper and team. The studs were of 2 by 6 in. lumber resting on a 2 by 6 in. sill and held at the top by a plate of the same size. A single layer of unmatched rough boards, lined with tarred paper, held in place by perpendicular slats, constituted the sheathing. The dirt was filled in against the sides. The silo had no roof, and the silage, covered with straw and 6 in. of moistened dirt, was well preserved.

STATISTICS.

Reports of director and of treasurer of New York State Station (*New York State Sta. Rpt. 1893, pp. 1–211*).—This includes a financial report for the fiscal year ending September 30, 1893; a brief survey of the work and list of bulletins for the year; the needs of the station; World's Fair exhibit of fruits and vegetables and awards to the station, and gifts to the station, together with reports on investigations of breeds of dairy cattle, sources of fat in milk, inspection of commercial fertilizers, and several other studies, all of which are noticed elsewhere under the appropriate headings.

Proceedings connected with the celebration upon the completion of the station building and the organization of the Sheep Breeders and Wool Growers' Association, the State Horticultural Society, and the State Dairy Association, April 5, 1894 (*West Virginia Sta. Special Bul. 2, pp. 82, figs. 17, pl. 1*).

Contribution to the statistics of the indebtedness of the farmers of lower Hesse, C. HUBACH (*Landw. Jahrb., 23 (1894), No. 6, pp. 1035–1043*).

NOTES.

California University and Station.—The State legislature at its recent session gave to the university a special appropriation of $250,000 for a building for the affiliated colleges. It abolished the State Viticultural Commission, to take effect January 1, 1896, transferred the duties of the commission, with a valuable library and set of instruments, to the station, and appropriated $5,000 to carry on its work during the next 2 years; the same appropriation was made for the forestry stations of the university. A dairy bureau has been established by the legislature for the purpose of preventing fraud in the sale of butter and cheese, and its analytical work will be done by the station.

The "alkali soil" question, especially covering the rise and fall of alkali in the soil at the Tulare station during wet and dry seasons and the amounts necessary to seriously affect plant growth, is a prominent subject of investigation, and an extensive series of analyses is being made. The value of the Australian salt bush (*Atriplex semibaccatum*) upon the alkali lands of the State, as food for sheep and cattle at least, has been demonstrated.

Prof. E. L. Greene, the botanist of the station, has resigned, to take effect in June.

During the past year the weight of station bulletins and reports distributed was about 10,000 lbs.

Minnesota University and Station.—A $40,000 dormitory and dining hall is to be erected for the school of agriculture.

Ample sheep and hog barns are to be erected this summer at the university farm, and the basement of the large experiment station barn is being entirely refitted for experiments in feeding dairy and beef cattle.

The dairy hall is to be enlarged this summer to more than twice its present capacity.

The Minnesota legislature, besides giving the agricultural department of the university $65,000 for buildings, appropriated $20,000 for procuring and equipping 2 subexperiment farms, and $10,000 for their maintenance during the current biennial period.

The entomologist of the station has been provided with $5,000 annually, with which to combat the insect pests of the State. The recent movement of the chinch bug into the wheat districts of this State have awakened the farmers to the need of a warfare upon this pest.

The fields of the university farm have been entirely replatted, each field being divided into series 8 rods wide with 16 ft. alleys between, thus providing plats ranging in size from one twentieth of an acre to 2 acres, for the various field trials.

Cornell University and Station.—Several horticultural schools provided under the State appropriation of $16,000 have already been held with very satisfactory results, under the direction of Prof. L. H. Bailey. The schools are from 1 to 5 days duration. Farmers are registered and required to participate in the work. Practical lessons are given in spraying nearby orchards and vineyards.

A great deal of interest is manifested in these schools by fruit growers, and from the number of schools held it seems evident that they are in advance of the good work done in this State by the farmers' institutes.

PERSONAL MENTION.—Dr. R. Sachsse, an agricultural chemist of wide reputation, died at Leipsic, April 25, 1895. Dr. Sachsse was a professor in the University of Leipsic and a frequent contributor to scientific agricultural journals. His book on agricultural chemistry, published in 1888, is widely known.

Dr. J. Brümmer, professor in the University of Jena, and director of the agricultural department of the experiment station of Jena, died March 14, 1895, at the age of 44 years.

Dr. A. von Planta died at Zurich, February 25, 1895, in his seventy-fifth year. Dr. von Planta was never connected officially with any institution but devoted his life to private study in chemical lines, especially the carbohydrates and the chemical activity of bees. A short account of Dr. von Planta's life and works is given by Prof. E. Schulze in *Landw. Vers. Stat., 46, No. 1, pp. 79–84.*

EXPERIMENT STATION RECORD.

VOL. VI. No. 12.

The present number completes the sixth volume of the Record. The extension of the Record work during the year is indicated by the following table, showing the amount of abstracting done for Volumes V and VI, respectively:

	Volume V.	Volume VI.
Station reports	43	42
Station bulletins	267	295
Publications of United States Department of Agriculture	67	78
Foreign articles	227	526
Total number of articles	973	1,606
Classified as follows:		
Chemistry	47	96
Botany	42	53
Bacteriology and zoölogy	10	6
Meteorology	36	86
Air, water, and soil	36	87
Fertilizers	72	95
Field crops	155	398
Horticulture	84	155
Forestry	10	22
Seeds and weeds	24	37
Diseases of plants	66	110
Entomology	71	99
Foods and animal production	119	182
Veterinary science	18	62
Dairying	89	113
Technology	4	6
Agricultural engineering	18	32
Statistics	69	65

The abstracts in this volume occupy 773 pages, and required in their preparation the reviewing of 28,263 pages in the original publications. In addition to this the volume contains 2,104 foreign titles, not abstracted; 20 editorials, occupying 29 pages; 11 special articles, occupying 138 pages, and 79 station notes, occupying 12 pages.

As in previous volumes, the subject index has been made in sufficient detail to serve as a fairly complete guide to the contents of the publications abstracted.

The classified list of abstracts has been omitted from this volume. The number of articles to be catalogued is so large that it is believed that in most cases references to a given subject will be more readily found in the detailed index than in a voluminous subject list of titles.

INDEX OF SUBJECTS.

Page.
Abelmoschus esculentus, notes, U. S. D. A 207
Abies balsamea, notes 143
  cephalonica, notes 143
  lasiocarpa, notes 143
  nobilis, notes 143
  nordmanniana, notes 143
  pectinata, abnormal bark formation 196
  pinsapo, notes 143
  siberica, notes 143
  webbiana, notes 143
Ablerus clisiocampæ, notes, U. S. D. A 562
Abortion in cattle 165
Abutilon avicennæ, notes, U. S. D. A 207
  fiber, notes, U. S. D. A 207
Acacia decurrens, notes 775
Acclimatization of plants 115
Acer campestre, notes 821
Acetic acid, effect on sucrose 868
  fermentation, studies 969
  test, Valenta 274
Achrœa grisella, notes 149
Acid constituents of wines 377
  content of malt, estimation 376
  phosphate, analyses 401
    Ala 401
    N. J 797
    Pa 798
    S. C 402
  solutions, standardization 182
Acidity of milk, determination 866
Acorns, cattle poisoning by 472
  insects affecting, U. S. D. A 440
Acridium peregrinum, parasites 151
  spp., parasites 151
Acrocystis batatas, notes, U. S. D. A 987
Actinomyces, gen., studies 80
  gruberi, n. sp 333
Actinomycosis. (*See* Lumpy jaw.)
Adalia bipunctata, notes 741
  U. S. D. A 652
Adimonia cavicollis, notes, U. S. D. A 652
Adulteration, need of statistics 573
  of bone meal, detection 134
    cattle food, N. C 569
    coffee 331
    drugs, U. S. D. A 573
    fertilizers and feeding stuffs 522
      detection 631
    food 331
      U. S. D. A 573

Page.
Adulteration of ground pepper 842
    kainit, detection 134
    milk 331
      detection 84
    olive oil, detection 1023
    Paris green 964
    phosphatic slag, detection 631
    spices 15
    sulphate of ammonia, detection 134
    sweet wine and honey 615
    wine 377
      tamarinds in 377
Æcidium asperfolii, notes 233
  punctatum parasitic on *Anemone ranunculoides* 436
Ægeria pyri, notes, U. S. D. A 313
Aërial roots of carnations 873
Ætroxys tabacum, notes, Ky 235
Agaricus arvensis, notes 728
  campestris, notes 728
  gambosus, notes 728
  melleus as a cause of pourridié of grapes 60
    on oak roots 1000
  nudus, notes 728
  personatus, notes 728
  prunulus orcella, notes 728
  rubescens, notes 728
  vaginatus, notes 728
Agave americana, notes 345
  culture and use 807
  rigida sisiliana, notes 278
Age of type and variability 488
Agricultural—
  appropriation bill 679
  charts of Ferté-sous-Jouarre France 23, 283
  chemistry 691
    treatise on 869
  Chemists, Association of Official 178, 614
  Colleges and Experiment Stations, convention 257, 486
